

VOLUME ONE

ENCYCLOPEDIA OF STRESS

SECOND EDITION

EDITOR-IN-CHIEF
GEORGE FINK

DEDICATION

For Ann Elizabeth

EDITOR-IN-CHIEF

George Fink

Professorial Research Fellow (formerly Director)
Mental Health Research Institute of Victoria
Parkville, Melbourne, Victoria
Australia
Formerly Director, MRC Brain Metabolism Unit
Edinburgh, Scotland, UK.

ASSOCIATE EDITORS

Bruce McEwen

The Rockefeller University
Laboratory of Neuroendocrinology
1230 York Avenue, Box 165
New York NY 10021

E. Ronald de Kloet

Universiteit Leiden
Natuurwetenschappen Wiskunde en
LACDR Medical Pharmacology
Einsteinweg 55, kamer HB 902
Leiden 2333 CC
The Netherlands

Robert Rubin

Department of Psychiatry (116A)
VA Greater LA Healthcare System
11301 Wilshire Blvd.
Los Angeles, CA 90073

George Chrousos

First Department of Pediatrics,
Athens University Medical School,
Aghia Sophia Children's Hospital,
115 27 Athens, Greece

Andrew Steptoe

University College London
Department of Epidemiology and Public Health
Psychology
1-19 Torrington Place London WC1E 6BT
UK

Noel Rose

Johns Hopkins University
Center for Autoimmune Disease Research
Molecular Microbiology and Immunology
615 North Wolfe Street, Rm E5014
Baltimore MD 21205

Ian Craig

SGDP Research Centre
Institute of Psychiatry, Molecular Genetics Group
De Crespigny Park, Box P082
Denmark Hill
London SE5 8AF
UK

Giora Feuerstein

Merck Research Laboratories 42-209
Department of Cardiovascular Diseases
770 Sumneytown Pike
West Point PA 19486

<i>Preface to the Second Edition</i>	<i>xxxiii</i>
<i>Guide to Encyclopedia</i>	<i>xxxv</i>
<i>Foreword</i>	<i>xxxvii</i>

VOLUME 1

A

Acute Stress Disorder and Posttraumatic Stress Disorder	1	Adrenal Medulla	52
R. Yehuda and C. M. Wong		R. Kvetnansky and R. McCarty	
Acute Stress Response: Experimental	7	Adrenaline	60
K. Pacak and R. McCarty		T. M. Pollard	
Acute Trauma Response	15	Adrenocortical Function, Factors Controlling Development Thereof	64
W. C. Chiu, D. E. Carlson and M. P. Lilly		T. Else and G. D. Hammer	
Adenylyl Cyclases and Stress Response	21	Adrenocorticotrophic Hormone (ACTH)	69
F. A. Antoni		M. E. Rhodes	
Adjustment Disorders	24	Aerobic Exercise and Stress Reduction	73
M. Dascalu and D. Svrakic		E. J. C. de Geus and J. H. Stubbe	
Adolescence	28	Affective Disorders	78
G. N. Swanson		D. F. MacKinnon	
Adolescent Suicide	36	Aggression	84
M. Berk, R. Suddath and M. Devich-Navarro		E. F. Coccaro and E. C. Manning	
Adrenal Cortex	38	Aggressive Behavior	89
G. P. Vinson, B. J. Whitehouse and J. P. Hinson		J. M. Koolhaas	
Adrenal Insufficiency	47	Aging and Adrenocortical Factors	92
H. S. Willenberg, S. R. Bornstein and G. P. Chrousos		C. Lord and J. C. Pruessner	
		Aging and Psychological Stress	96
		B. W. J. Penninx	
		Aging and Stress, Biology of	102
		M. A. Horan, R. N. Barton and G. J. Lithgow	
		AIDS	108
		M. H. Antoni and D. G. Cruess	
		Airline Accidents	114
		G. Li	
		Alarm Phase and General Adaptation Syndrome	119
		R. McCarty and K. Pacak	

Bereavement	317	Caregivers, Stress and	416
P. J. Clayton		S. H. Zarit, K. Bottigi and J. E. Gaugler	
Beta-Adrenergic Blockers	323	Catecholamines	419
M. B. Hamner and G. W. Arana		U. Lundberg	
Beta-Endorphin	332	Central Stress Neurocircuits	424
M. Lee and S. L. Wardlaw		S. Kollack-Walker, H. E. W. Day and H. Akil	
Blood Pressure	335	Cerebral Metabolism, Brain Imaging	432
A. Sherwood and R. A. Carels		K. P. Ebmeier, C. L. Donaghey and N. J. Dougall	
Blood-Brain Barrier, Stress and	342	Chaperone Proteins and Chaperonopathies	438
S. N. Malaeb and B. S. Stonestreet		A. J. L. Macario and E. Conway de Macario	
Borderline Personality Disorder	348	Chaperonopathies	444
H. W. Koenigsberg and L. J. Siever		A. J. L. Macario and E. Conway de Macario	
Brain and Brain Regions	351	Chemical Warfare	449
A. G. Watts		J. Berberich	
Brain Natriuretic Peptide (BNP)	357	Chernobyl, Stress Effects of	452
P. Pervanidou and G. P. Chrousos		A. Tønnessen and L. Weisæth	
Brain Trauma	360	Child Abuse	457
B. Pentland		C. C. Swenson and L. Saldana	
Breast Cancer	364	Child Physical Abuse	460
A. Moyer		C. C. Swenson	
Burnout	368	Child Sexual Abuse	463
C. Maslach and M. P. Leiter		J. A. Cohen	
		Childbirth and Stress	467
		S. Ayers and E. Ford	
		Childhood Stress	472
		S. Sandberg	
		Cholesterol and Lipoproteins	478
		C. M. Stoney	
		Chronic Fatigue Syndrome	484
		A. J. Cleare and S. Wessely	
		Chronic Social Stress: GR Sensitivity in Leukocytes	493
		A. Weizman and B. Rotberg	
		Circadian Clock Genes as Modulators of Sensitivity to Genotoxic Stress	496
		M. P. Antoch and R. V. Kondratov	
		Circadian Rhythm Effects on Cardiovascular and Other Stress-Related Events	500
		R. Manfredini, B. Boari, R. Salmi, A. M. Malagoni and F. Manfredini	
Calbindin	373		
F. A. Antoni			
Calcium, Role of	374		
F. A. Antoni			
Calcium-Dependent Neurotoxicity	375		
J. S. Kelly			
Cancer	378		
D. Spiegel			
Cancer Treatment	384		
F. I. Fawzy, A. L. Canada and N. W. Fawzy			
Captivity, Adaptation to	388		
R. H. Rahe			
Captivity, Recovery from	392		
R. H. Rahe			
Cardiovascular System and Stress	396		
P. Hjelm Dahl			
Cardiovascular Disease, Stress and	410		
G. P. Chrousos and G. Kaltsas			

C

Circadian Rhythms, Effects of Prenatal Stress in Rodents	505	Corticosteroids and Stress	613
S. Maccari and O. Van Reeth		A. Munck	
Circadian Rhythms, Genetics of	508	Corticotropin Releasing Hormone (CRH)	620
F. W. Turek and M. H. Vitaterna		A. T. Lim	
Cognition and Stress	513	Corticotropin Releasing Factor Receptor Deficiency in Mice	623
M. W. Eysenck		N. J. Justice and K.-F. Lee	
Cognitive-Behavioral Therapy	515	Corticotropin Releasing Factor-Binding Protein	627
G. A. Fava		P. J. Lowry, C. F. Kemp and R. J. Woods	
Combat Reaction, Chronic	518	Corticotropin-Releasing Factor Circuitry in the Brain – Relevance for Affective Disorders and Anxiety	630
R. H. Rahe		D. A. Gutman and C. B. Nemeroff	
Combat Stress Reaction	524	Corticotropin-Releasing Factor (CRF) Family of Neuropeptides – Role in Inflammation	635
M. Dobson		A. Gravanis and A. N. Margioris	
Combat, Acute Reactions to	529	Corticotropin-Releasing Factor Receptors	641
R. H. Rahe		D. E. Grigoriadis	
Common Cold and Stress	533	Cortisol Awakening Response	649
A. Smith		A. Steptoe	
Community Studies	536	C-Reactive Protein	653
C. J. Holahan, R. H. Moos and L. M. Groesz		W. J. Kop and A. A. Weinstein	
Comorbid Disorders and Stress	542	Crime Victims	659
S. Sundram and Avril Pereira		I. Robbins	
Comparative Anatomy and Physiology	549	Crisis Intervention	662
A. G. Watts		D. Hamaoka, D. Benedek, T. Grieger and R. J. Ursano	
Concentration Camp Survivors	553	Critical Thermal Limits	667
J. D. Kinzie		J. Roth	
Congenital Adrenal Hyperplasia (CAH)	556	Crowding Stress	669
A. Solomon and P.-M. G. Bouloux		L. Kovács and P. Csermely	
Conservation of Resources Theory	562	Cultural Factors in Stress	672
S. E. Hobfoll and J. S. Ford		J. W. Berry and B. Ataca	
Control and Stress	568	Cultural Transition	678
A. Steptoe		M. S. Kopp	
Coping and Stress: A Lens and Filter Model	574	Cushing's Syndrome, Medical Aspects	682
R. H. Rahe		S. R. Bornstein, M. Gruber, H. S. Willenberg, C. A. Stratakis and G. P. Chrousos	
Coping Skills	578	Cushing's Syndrome, Neuropsychiatric Aspects	688
A. DeLongis and E. Puterman		M. N. Starkman	
Corticosteroid Receptor Genes: Functional Dissection in Mice	584	Cytokines	692
F. Tronche		G. D. Marshall	
Corticosteroid Receptors	594		
O. C. Meijer, E. R. de Kloet and B. S. McEwen			
Corticosteroid-Binding Globulin (Transcortin)	605		
B. E. P. Murphy			

Cytokines, Chronic Stress, and Fatigue S. Jain and P. J. Mills	698	Diet and Stress, Non-Psychiatric J. Wardle and E. L. Gibson	797
Cytokines, Stress, and Depression B. E. Leonard and C. Song	705	Diet and Stress, Psychiatric V. March and M. H. Fernstrom	806
Cytotoxic Lymphocytes M. A. Fletcher and N. G. Klimas	711	Disaster Syndrome P. Valent	811
D		Disasters and Mass Violence, Public, Effects of G. Stevens, B. Raphael and M. Dobson	814
Death Anxiety R. Kastenbaum	717	Disease, Stress Induced H. S. Willenberg, S. R. Bornstein and G. P. Chrousos	824
Defensive Behaviors D. C. Blanchard, M. Yang, M. Hebert and R. J. Blanchard	722	Dissociation J. R. Maldonado	828
Demand–Control Model T. Theorell	727	Distress G. Matthews	838
Dental Stress T. K. Fábán, G. Fábán and P. Fejérdy	733	Divorce, Children of K. N. Hipke, S. A. Wolchik and I. N. Sandler	844
Depersonalization: Systematic Assessment M. Steinberg	736	Domestic Violence B. Donohue, H. Hill and T. Maier-Paarlberg	848
Depression and Coronary Heart Disease F. Lespérance and N. Frasure-Smith	741	Dopamine, Central G. D. Stanwood	852
Depression and Manic–Depressive Illness R. T. Rubin and B. J. Carroll	744	<i>Drosophila</i> Genes and Anoxia G. G. Haddad	859
Depression and Stress, Role of n-3 and n-6 Fatty Acids C. Song and B. E. Leonard	754	<i>Drosophila</i> Studies M. Allikian and J. Tower	864
Depression Models K. Matthews and C. Stewart	760	Drug Use and Abuse J. R. Mantsch	866
Depression, Immunological Aspects M. R. Irwin	766	E	
Dermatological Conditions M. A. Gupta	773	Earthquakes, Stress Effects of M. Livanou and M. Başoğlu	871
Desensitization F. A. Antoni	778	Eating Disorders and Stress D. C. Jimerson	876
Dexamethasone Suppression Test (DST) R. T. Rubin and B. J. Carroll	780	Eclampsia and Pre-Eclampsia A. Makrigiannakis, G. Petsas and G. P. Chrousos	880
DEX-CRH Test N. C. Schommer and I. Heuser	784	Economic Factors and Stress R. A. Catalano	884
DHEA J. Herbert	788	Education Levels and Stress J. Mirowsky and C. E. Ross	888
Diabetes, Type 1 A. Riazi and C. Bradley	792		

Food Shift Effect F. K. Stephan	88	Glucocorticoid Receptor Mutations and Polymorphisms J. W. Koper	183
Freud, Sigmund D. J. Lynn	90	Glucocorticoids – Adverse Effects on the Nervous System R. M. Sapolsky	185
G		Glucocorticoids, Effects of Stress on J. C. Buckingham	190
GABA (Gamma Aminobutyric Acid) J. D. C. Lambert	97	Glucocorticoids, Overview B. E. Pearson Murphy	198
Gastrointestinal Effects R. Murison and A. M. Milde	109	Glucocorticoids, Role in Stress J. C. Buckingham	210
Gender and Stress R. J. Handa and W. C. J. Chung	115	Glucose Transport A. L. McCall	217
Gene–Environment Interactions in Early Development I. S. P. Davis and R. Plomin	122	Glycobiology of Stress G. Lauc and M. Flögel	222
Genetic Factors and Stress C. A. Koch and C. A. Stratakis	128	Gonadotropin Secretion, Effects of Stress on M. Ferin	228
Genetic Polymorphisms in Stress Response I. W. Craig	135	Graves' Disease (Thyrotoxicosis) W. M. Wiersinga	234
Genetic Predispositions to Stressful Conditions D. Blackwood and H. Knight	141	Grieving A. Ray and H. Prigerson	238
Genetic Testing and Stress V. Senior and M. Cropley	146	Group Therapy N. Wong	242
Genetic Variation of HPA Axis Activity and Function in Farm Animals P. Mormède	150	Gulf War Syndrome, Psychological and Chemical Stressors H. Soreq	248
Ghrelin and Stress Protection T. Brzozowski, M. Pawlik, D. Drozdowicz, Z. Sliwowski, S. J. Konturek, W. W. Pawlik and P. C. Konturek	153	H	
Glia or Neuroglia G. W. Bennett and D. E. Ray	161	Health and Socioeconomic Status T. Chandola and M. Marmot	255
Glucocorticoid Effects on Memory: the Positive and the Negative O. T. Wolf	166	Health Behavior and Stress A. Steptoe	262
Glucocorticoid Negative Feedback M. F. Dallman	172	Heart Disease/Attack G. J. Baker, S. Suchday and D. S. Krantz	266
Glucocorticoid Receptor Mutant Mice as Models for Stress-Induced Affective Disorders P. Gass	176	Heart Failure, Stress Effects M. Alevizaki and G. P. Chrousos	272
		Heart Rate J. R. Jennings	274
		Heat Resistance A. J. L. Macario and E. Conway de Macario	278

Heat Shock Genes, Human	284	Hyperthermia	381
A. J. L. Macario and E. Conway de Macario		J. Roth	
Heat Shock Proteins: HSP60 Family Genes	288	Hyperthyroidism	388
H. Kubota		I. M. Lesser and D. L. Flores	
Heat Shock Response, Overview	292	Hyperventilation	390
A. J. L. Macario and E. Conway de Macario		C. Bass	
Hemostasis and Stress	300	Hypnosis	394
Roland von Känel		W. G. Whitehouse, E. C. Orne and M. T. Orne	
Herpesviruses	305	Hypocortisolism and Stress	400
D. A. Padgett, M. T. Bailey and J. F. Sheridan		C. M. Heim and U. M. Nater	
Hippocampal Neurons	311	Hypoglycemia	408
R. L. Spencer and S. T. Bland		B. M. Frier	
Hippocampus, Corticosteroid Effects on	321	Hypotension, Hypovolemia, and Septic Shock	413
M. Joëls and H. Karst		A. Beishuizen, A. B. Johan Groeneveld and I. Vermes	
Hippocampus, Overview	327	Hypothalamic-Pituitary-Adrenal Axis	421
M. J. Meaney and S. J. Lupien		M. F. Dallman, S. Bhatnagar and V. Viau	
Hiroshima Bombing, Stress Effects of	332	Hypothermia	428
R. J. Lifton		M. J. Taylor	
HIV Infection/AIDS	336	Hypothyroidism	439
B. W. Dixon		R. T. Joffe	
Holocaust Survivors, Experiences of	339	Hysteria	442
P. Valent		K. Pajer	
Holocaust, Stress Effects of	342		
P. Valent			
Homeostasis	347		
B. S. McEwen			
Homosexuality, Stress and	348	Immobilization Stress	445
J. Drescher		R. Kvetnansky and R. McCarty	
Hostility	354	Immune Cell Distribution, Effects of Stress on	449
L. H. Powell and K. Williams		F. S. Dhabhar	
HPA Alterations in PTSD	359	Immune Function, Stress-Induced Enhancement	455
R. Yehuda		F. S. Dhabhar	
Hurricane Katrina Disaster, Stress Effects of	364	Immune Response	462
C. Piotrowski		P. J. Delves	
11β-Hydroxysteroid Dehydrogenases	368	Immune Suppression	470
J. R. Seckl		P. Prolo and F. Chiappelli	
Hyperreactivity (Cardiovascular)	372	Immune Surveillance – Cancer, Effects of Stress on	477
A. Georgiades		D. Spiegel and F. S. Dhabhar	
Hypertension	376	Immune System, Aging	481
A. Steptoe		M. A. Horan	

Immunity	485	L	
F. Chiappelli			
Impact of Terrorism on the Development of Mental Health Symptoms	493	Learned Helplessness	567
R. Yehuda		D. M. Isaacowitz and M. E. P. Seligman	
Impotence, Stress and	497	Learning and Memory, Effects of Stress on	571
M. R. Gignac, G. M. Rooker and J. K. Cohen		M. Lindau, O. Almkvist and A. H. Mohammed	
Impulse Control	500	Left Ventricular Mass	577
I.-M. Blackburn		T. G. Pickering	
Incest	502	<i>Leishmania</i>, Stress Response in	579
A. P. Mannarino		M. Shapira	
Income Levels and Stress	506	Leptin, Adiponectin, Resistin, Ghrelin	584
S. V. Subramanian and I. Kawachi		A. Gavrilu, D. Barb and C. S. Mantzoros	
Indigenous Societies	511	Leukocyte Trafficking and Stress	592
W. W. Dressler		S. Hong, M. U. Goebel and P. J. Mills	
Industrialized Societies	517	Life Events and Health	599
J. Siegrist		P. Surtees and N. Wainwright	
Infection	521	Life Events Scale	603
H. Friedman and S. H. Pross		E. Wethington	
Inflammation	530	Lockerbie Air Crash, Stress Effects of	608
G. Z. Feuerstein, R. R. Ruffolo, C. Coughlin, J. Wang and D. Miller		H. Livingston and M. Livingston	
Instinct Theory	535	Loss Trauma	612
R. Gardner Jr.		A. Bifulco	
Integrative Medicine (Complementary and Alternative Medicine)	537	Lymph Nodes	616
D. Spiegel		T. L. Whiteside	
Interactions Between Stress and Drugs of Abuse	540	Lymphocytes	622
P. V. Piazza and M. Le Moal		N. R. Rose	
J		M	
Job Insecurity: The Health Effects of a Psychosocial Work Stressor	549	Macrophage Antimycobacterial Activity, Effects of Stress on	629
J. E. Ferrie and P. Martikainen		C. S. Boomershine and B. S. Zwilling	
K		Macrophages	634
Kidney Function	557	W. P. Fehder, F. Tuluc, W.-Z. Ho and S. D. Douglas	
W. J. Welch		Major Depressive Disorder	640
Korean Conflict, Stress Effects of	563	A. B. Negrão and P. W. Gold	
C. A. Goguen and M. J. Friedman		Male Partner Violence	645
		M. Ingram, N. P. Yuan and M. P. Koss	
		Marital Conflict	651
		P. T. McFarland and A. Christensen	

Marital Status and Health Problems	653	Mitochondria	754
I. M. A. Joung		I. Manoli, S. Alesci and G. P. Chrousos	
Marriage	660	Monoamine Oxidase	761
A. C. Yoneda and J. Davila		P. Huezo-Diaz and I. W. Craig	
Maternal Deprivation	667	Motor Vehicle Accidents, Stress Effects of	764
R. L. Huot, C. O. Ladd and P. M. Plotsky		T. C. Buckley and E. B. Blanchard	
Medical Profession and Stress	674	Mucosal Secretory Immunity, Stress and	768
K. G. Power and V. Swanson		J. A. Bosch and D. Carroll	
Meditation and Stress	678	Multi Drug Resistance P Glycoprotein and other Transporters	774
J. L. Kristeller		E. C. M. de Lange	
Membrane Glucocorticoid Receptors	686	Multiple Personality Disorder	783
P. J. Gasser and M. Orchinik		R. P. Kluft	
Memory and Stress	693	Multiple Sclerosis	790
S. J. Lupien and F. S. Maheu		A. T. Reder	
Memory Impairment	699	Multiple Trauma	795
A. J. Parkin [†]		P. N. Soucacos and E. O. Johnson	
Menopause and Stress	703	Musculoskeletal Problems and Stress	800
N. E. Avis		S. Svebak	
Menstrual Cycles and Stress	706	Myopathy	807
R. Suri and L. Altshuler		G. A. Small	
Mental Stress Testing	712		
P. G. Saab, K. A. Kline and J. R. McCalla			
Metabolic Syndrome	717	Natural Killer (NK) Cells	815
L. Keltikangas-Järvinen		T. L. Whiteside, M. Boyiadzis and R. B. Herberman	
Metabolic Syndrome and Stress	721	Negative Affect	822
R. Rosmond		A. A. Stone and A. A. Gorin	
Metals, Oxidative Stress, and Brain Biology	724	Neighborhood Stress and Health	825
D. I. Finkelstein, T. Lynch, S. Wilkins, R. A. Cherny and A. I. Bush		A. V. Diez Roux	
Metastasis	726	Nelson's Syndrome	828
M. K. Demetrikopoulos		A. Stathopoulou, K. Dimitriou and G. Kaltsas	
Metyrapone: Basic and Clinical Studies	730	Neural Stem Cells	832
E. A. Young		U. S. Sohur, J. G. Emsley, B. D. Mitchell and J. D. Macklis	
Migraine	733	Neurodegenerative Disorders	840
N. M. Ramadan		M. F. Mendez and A. M. McMurtry	
Mineralocorticoid Receptor Polymorphisms	744	Neurodevelopmental Disorders in Children	844
R. H. DeRijk and E. R. de Kloet		N. J. Rinehart and B. J. Tonge	
Minorities and Stress	748	Neuroendocrine Systems	851
I. Mino, W. E. Profit and C. M. Pierce		G. Fink	
		Neurogenesis	865
		P. Tanapat and E. Gould	

[†]Deceased.

Pheromones	119	Prison	217
A. Kumar, C. A. Dudley, S. Chakravarty and R. L. Moss		D. L. Whitehead and A. Steptoe	
Pituitary Regulation, Role of	127	Prisoners of War	223
F. A. Antoni		C. Tennant	
Police, Stress in	131	Problem-Solving Skills Training	227
R. J. Burke		A. M. Nezu, C. M. Nezu and T. J. D’Zurilla	
Posttraumatic Stress Disorder – Clinical	135	Prolactin and Stress	231
N. C. Feeny, L. R. Stines and E. B. Foa		G. Tolis, G. Rombopoulos, D. Kaltsas, E. Katounda, V. Kaltzidou and N. Angelopoulos	
Posttraumatic Stress Disorder – Neurobiological basis for	140	Pro-opiomelanocortin (POMC)	233
M. Barad		A. B. Bicknell	
Posttraumatic Stress Disorder in Children	145	Prostaglandins	240
A. M. La Greca		S. Moshonov, U. Zor and Z. Naor	
Posttraumatic Stress Disorder, Delayed	150	Proteases in Prokaryotes and Eukaryotic Cell Organelles	247
A. Holen		E. Conway de Macario and A. J. L. Macario	
Posttraumatic Stress Disorder, Neurobiology of	152	Proteases in the Eukaryotic Cell Cytosol	252
J. D. Bremner		E. Conway de Macario and A. J. L. Macario	
Posttraumatic Therapy	157	Protein Synthesis	258
A. M. Rasmusson, C. M. Monson and P. A. Resick		M. A. Brostrom and C. O. Brostrom	
Pregnancy – Maternal and Perinatal Stress – Effects of	165	Proteosome	266
P. Smirnaki and M.-A. Magiakou		M. Maldonado and J. Wang	
Premenstrual Dysphoric Disorder	173	Psoriasis	271
S. Nowakowski, P. Haynes and B. L. Parry		A. B-. Kirschbaum	
Pre-pulse Inhibition	180	Psychoanalysis	274

PREFACE TO FIRST EDITION

“Stress” remains one of the most frequently used but ill-defined words in the English language. Stress is a phenomenon that has quite different meanings for the politician, social scientist, physician, nurse, psychotherapist, physiologist, molecular biologist, and perhaps you and me. This diversity of meanings was one impetus for creating the *Encyclopedia of Stress*, the aim being to derive a definition of stress from a variety of expert descriptions. The second impetus was the obvious need for an up-to-date compendium on one of the most important social, medical, and psychological phenomena of our age. We were fortunate in attracting stars for our Editorial Board and a set of most distinguished contributors for the 400 or so entries—indeed, the list of contributors is a Who’s Who in stress research.

We anticipate that the diversity of our readers will equal the diversity of the topics covered. They will find that the coverage of the Encyclopedia extends well beyond the general adaptation theory of Hans (Janos) Selye and the fight-or-flight response of Walter Cannon. Nevertheless, the general principles annunciated by these two great pioneers in the field still underpin our understanding of the biology of the stress phenomenon. That is, stress is a real or perceived challenge, either endogenous or exogenous, that perturbs body equilibrium or “homeostasis.” The stressor may range from overcrowding, traffic congestion, violence, bereavement, redundancy, or unemployment to physical, chemical, biological, or psychological insults. Whether the person can adapt to or cope with the stress will depend on the nature and severity of the stressor and the person’s physical and mental state, which in turn depends on genetic, experiential, social, and environmental factors. These issues are discussed in depth in the Encyclopedia, as are the mechanisms of coping and the impact of stress on health and predisposition to diseases such as

cancer, infection, rheumatoid arthritis, heart disease, high blood pressure, and mental disorder.

Aggression remains a hallmark of human behavior, even as we move into the third millennium, and so the Encyclopedia covers several topical areas that have only recently been analyzed systematically. These include war and specific wars, posttraumatic stress disorder (PTSD; formerly thought of vaguely as “shell shock”), rape, torture, marital discord and spousal abuse, and the Holocaust. In tackling these topics we accept that our entries may not include all the nuances that are necessary for a full understanding of what these phenomena are all about and described so graphically and sensitively in Tolstoy’s *War and Peace* or Pat Barker’s monumental *Regeneration* trilogy on the horrific psychological traumas of the First World War. Nevertheless, an important start has been made in that we now accept that PTSD is not just a lack of “bottle” (courage or “guts”), but rather a syndrome that needs to be and can be understood within the framework of medicine and psychology.

Biologically, the stress response reflects a set of integrated cascades in the nervous, endocrine, and immune defense systems. As in most areas of biology, molecular genetics has made a significant difference in the precision with which we now understand the physiopathological processes of the stress response. And so the adage formerly applied to diabetes mellitus may now apply equally to stress: “Understand stress and you will understand medicine.”

In summary, we hope that this first *Encyclopedia of Stress* will indeed define the phenomenon and at the same time provide a valuable source of information on a phenomenon that affects us all. In setting out on this adventure we were aware that there is nothing new under the sun and that stress has been around since the first biological particles, bacteria, or even viruses competed for the same mechanisms of replication.

There is a tendency for each generation to imagine that stress and its untoward effects are uniquely harsh for them, but it is not this misconception that underlies this work. Rather, the stress of “stress” itself—the massive accumulation of knowledge—made it seem propitious to bring the information together in a systematic manner that allows ready access to all who need or wish to understand the phenomenon.

The idea of producing this Encyclopedia was conceived at an Academic Press reception in San Diego held in conjunction with the annual meeting of the Society for Neuroscience in 1996. I am deeply indebted to Erika Conner for enabling conversion of the idea to a concept and then a project and to

Jennifer Wrenn, Christopher Morris, and Carolan Gladden, all of Academic Press, for their enthusiasm, encouragement, and herculean efforts that converted the concept into a reality. For giving generously of their intellect, expertise, sound advice, and unstinting work, I am greatly indebted to my friends and colleagues on the Editorial Board, who made the project such a satisfying experience. To all our contributors go our profound thanks for taking time out from wall-to-wall schedules to produce their entries, which together have made this Encyclopedia.

George Fink
August 1999

PREFACE TO THE SECOND EDITION

The popularity of the first edition of the Encyclopedia of Stress, the several major stressful conflicts that have occurred since 1999, and the significant advances in our knowledge of stress prompted the production of this second edition. In addition to more than 140 new articles, most of the original 400 first edition articles have been updated for the second edition to reflect, for example, advances in our understanding of corticotropin releasing factor (CRF) and urocortin receptors, ideas about the role of central CRF in the overall control of the psychological/mental as well as neuroendocrine response to stress, and the novel discoveries of the complex neuropeptide regulation of hunger and satiety. The effects of maternal and perinatal stress on subsequent body development and function in the adult, the adverse effects of stress on brain (and particularly hippocampal memory function), the role of the amygdala in fear and aggression, and the role of stress in the etiology of obesity and the metabolic syndrome all feature prominently in this new edition. 9/11 and the many new conflicts since 1999 have engendered new articles on terrorism, suicide bombers and their effects, as well as a retrospective on previous human apocalypses such as Hiroshima. Coverage of the whole field of post traumatic stress disorder (PTSD) has been expanded, reflecting the greater recognition and understanding of PTSD, and possibly related disorders such as *combat fatigue* and *burnout*. Stress and depression and anxiety, already touched on in the first edition, now feature prominently. On the conceptual side, *allostasis* (modified from Hans Selye's *heterostasis*), or stability through centrally regulated change in physiological set points, receives greater emphasis than it did in the first edition.

Overall, our understanding of stress mechanisms in the human has benefited from two major quantum leaps in technology. First, the advances in molecular genetics and genomics and sequencing of the human

genome (published after the first edition had appeared) have increased the rigor and precision of our understanding of the molecular neurobiology of stress. Thus, new to the second edition are a series of articles on the genetic factors that play a role in susceptibility to stress and in various components of the stress response. Secondly, functional brain imaging has enhanced our understanding of the neurobiology of stress in the human. Many of the articles in the second edition reflect the positive impact of these two advances.

Accessibility to the second edition of the Encyclopedia of Stress will be facilitated by virtue of the fact that it is published online as well as in hard copy. My profound thanks for their selfless work go to our team of distinguished authors and to my friends and colleagues on the Editorial Board. Production of the Encyclopedia would not have been possible without our colleagues at Elsevier, and in particular Bob Donaldson and Hilary Rowe whose dedication, commitment and excellent work I am pleased to acknowledge.

November 2006

Note on Terminology of Corticotropin Releasing Factor/Hormone and the Catecholamines

The central nervous regulation of the anterior pituitary gland is mediated by substances, mainly peptides, which are synthesized in the hypothalamus and transported to the gland by the hypophyseal portal vessels. Because these compounds are transported by the blood, the term "hormone" gained acceptance in the neuroendocrine literature. The major hypothalamic peptide involved in the stress response is the

41-amino acid corticotropin releasing factor (CRF). The Endocrine Society (USA), following convention, adopted the term corticotropin releasing hormone (CRH). However, this nomenclature has been challenged. Hauger et al. (*Pharmacol Rev* 55: 21–26, 2003), in liaison with the International Union of Pharmacology Committee on Receptor Nomenclature and Drug Classification, argued that the CRF's function extends well beyond the biology of a hormone, and that therefore it should be termed corticotropin releasing factor (CRF) rather than hormone. Since the terminology of CRF versus CRH has yet to be resolved, the two terms and abbreviations are here used interchangeably, depending on author preference.

Adrenaline and *noradrenaline* are catecholamines that play a pivotal role in the stress response. These

terms are synonymous with *epinephrine* and *norepinephrine*, respectively. Both sets of terms are used interchangeably in the endocrine, neuroendocrine and stress literature, and this principle has been adopted for the Encyclopedia. Style has depended on author preference, but wherever possible within-article consistency has been ensured.

FOREWORD

This is the second edition of the *Encyclopedia of Stress*, the three heavy volumes that first appeared in 2000 under the overall editorial guidance of George Fink. From its original coining in reference to rather unusual and unpleasant situations, the word *stress* is now quasi synonymous with *life*, i.e. modern life! This second edition of the *Encyclopedia of Stress* presents several hundreds of articles written by experts in that particular field, especially for this series, discussing, clarifying, explaining to the average-reader as well as to anyone more educated in one field or another, the extraordinary involvement of stress and our normal or abnormal reactions to it, both in our physical body and its accompanying mind. The table of contents is truly amazing, from the stress of being born to the stress of dying and so many circumstances in between, with clear presentations of the pertinent, current knowledge about them. This is truly an encyclopedia where, surely, you will find some explanation and answer to your own stresses (and those of others).

Introduction

Relationship between Acute Stress Disorder (ASD) and Posttraumatic Stress Disorder (PTSD)

Epidemiology

Risk Factors for ASD and PTSD

Comorbid Disorders

Biological Findings in ASD and PTSD

Treatment of ASD and PTSD

Summary

Glossary

Acute stress disorder

A mental condition that can occur following exposure to extreme stress or trauma but by definition does not last longer than 1 month [i.e., after 1 month, if the symptoms persist, it is appropriate to consider the diagnosis of posttraumatic stress disorder (PTSD)].

Avoidant symptoms

Experiences that represent measures taken by the individual to avoid feeling, thinking, or coming into contact with reminders of the trauma; these experiences can also include having difficulty recalling important events of the trauma, avoiding people and places associated with the trauma, and generally feelings of emotional numbness, detachment from others, and feeling like there is no future.

Depersonaliza- tion

An alteration in the perception or experience of the self so that one feels detached

Derealization

from, and, as if one is an outside observer of, one's mental processes or body (e.g., feeling like one is in a dream).

Dissociation

An alteration in the perception or experience of the external world so that it seems strange or unreal (e.g., people may seem unfamiliar or mechanical).

A disruption in the usually integrated functions of consciousness, memory, identity, or perception of the environment. The disturbance may be sudden or gradual, transient, or chronic.

Dysphoria

An unpleasant mood such as sadness, anxiety, or irritability.

Flashback

A recurrence of a memory, feeling, or perceptual experience from the past.

Hyperarousal symptoms

Experiences that involve more physical reactions to trauma, including difficulty with sleep and concentration, irritability, and anger, needing to be on guard overly much, and having an exaggerated startle response to unexpected noises.

Intrusive symptoms

Experiences in which trauma survivors relive the trauma or become distressed by reminders of the trauma. These include unwanted thoughts and images, nightmares and bad dreams, extreme distress when exposed to a trigger or reminder, and a physiological response to triggers, including palpitations, sweating, and shortness of breath.

Posttraumatic stress disorder

A mental condition that can occur following exposure to extreme stress or trauma and lasts for 1 month or longer. Acute PTSD lasts from 1 to 3 months according to current formulations in the DSM-IV. Chronic PTSD lasts 3 or more months according to current formulations in the DSM-IV. In delayed onset PTSD, the onset of symptoms begins 6 or more months after the traumatic event(s) according to current formulations in the DSM-IV.

<i>Stressor</i>	In this context, it is a life event or life change that is so challenging as to potentially be associated with the onset, occurrence, or exacerbation of a psychological symptom or a mental disorder.
<i>Traumatic event</i>	According to DSM-IV, an experience that involves death or serious injury or another threat to one's physical integrity. A person does not need to actually experience the physical injury to be traumatized – just the knowledge that a person could have been severely injured or had a serious threat of injury and the feelings that accompany this realization are enough to produce a posttraumatic reaction.

Both acute stress disorder (ASD) and posttraumatic stress disorder (PTSD) are conditions that can occur in people who have been exposed to a traumatic life event. Traumatic events are thought to occur in at least 50% of the population. A traumatic event is defined in the *American Psychiatric Association's Diagnostic and Statistical Manual for Mental Disorders*, 4th edn (DSM-IV) as an experience in which a person underwent, witnessed, or was confronted with "an event that involved actual or threatened death or serious injury, or a threat to the physical integrity of self or others" and a subjective response of "intense fear, helplessness, or horror." The definition of trauma is purposely identical for both ASD and PTSD because what differentiates the two conditions is the point in time following the event at which the symptoms are experienced. Not all people who have experienced trauma will develop ASD and/or PTSD. ASD defines the immediate response to trauma for up to 4 weeks posttrauma, whereas PTSD encompasses a more chronic response to trauma beginning 1 month after the trauma and lasting at least 1 month after that. Recent estimates suggest that as much as 14% of persons in the United States will develop these conditions at some point during their lives. Given the chronic nature of PTSD and the extreme disability that can be associated with this condition, this statistic is alarming and points to PTSD as a major public health problem.

Introduction

Posttraumatic stress disorder was originally defined in 1980 to describe long-lasting symptoms that occur in response to trauma. The diagnosis revived psychiatry's long-standing interest in how stress can result in behavioral and biological changes that ultimately lead to disorder. At the time the formal diagnosis of PTSD was being conceptualized, the field was focused heavily on describing the psychological consequences

of combat Vietnam veterans and others who had chronic symptoms following exposure to events that had occurred years and even decades earlier. It was widely assumed that the symptoms that persisted in these survivors were extensions of those that were present in the earlier aftermath of a traumatic event. Indeed, some data from recently traumatized burn victims supported the idea that symptoms such as intrusive thoughts were present in the early aftermath of a trauma. However, at the time the diagnosis was established, there were no longitudinal data – either retrospective or prospective – that formally established the relationship between acute vs chronic posttraumatic symptoms.

Chronic PTSD was not initially conceptualized as being qualitatively different from what might have been observable in trauma survivors in the acute aftermath of the trauma. Rather, chronic PTSD suggested a failure of restitution of the stress response. The implicit assumption behind the diagnosis was that most trauma survivors initially developed symptoms as a direct result from exposure to the event.

As the awareness of the longterm effects of trauma became more widespread, investigators began to explore the reaction of trauma survivors in the immediate aftermath of the event. Studies of the acutely traumatized revealed that survivors do experience symptoms in the immediate aftermath. Clinicians felt it important to provide mental health interventions as early as possible so as to perhaps prevent the development of more chronic conditions. ASD first appeared as a diagnosis in the DSM-IV in 1994 in order to provide a diagnosis for people before they were eligible to receive the diagnosis of PTSD (i.e., having symptoms for less than 1 month's duration). Thus, ASD arose in part out of the need for justification for acute intervention. However, as described later, the syndrome of ASD has features that are not directly associated with the more chronic response of PTSD.

One of the important findings to be generated from research in the last two decades is that PTSD does not occur in everyone exposed to trauma, nor is PTSD the only possible response to trauma. Prospective longitudinal studies have now demonstrated that mood and other anxiety disorders can also occur following a traumatic event, and these may be present even in the absence of PTSD. The question of why some people develop PTSD and others do not has not been fully resolved and is the subject of current investigation in the field. However, insofar as this condition no longer serves to characterize a universal stress response, it has been important to redefine the nature of traumatic stress responses and determine the risk factors for developing these conditions. It has also

been important to consider the relationship between acute and chronic stress response.

Relationship between Acute Stress Disorder (ASD) and Posttraumatic Stress Disorder (PTSD)

Figure 1 shows a time continuum that describes the onsets of ASD and acute, chronic, and delayed PTSD. In ASD, symptoms must last for at least 2 days up to 4 weeks. In PTSD, the symptoms last for a period of at least a month following the traumatic event(s) and can be either acute (symptom duration of 3 months or less) or chronic (symptom duration of more than 3 months). The onset of PTSD can be delayed for months and even years.

Proponents of ASD hoped the diagnosis would help survivors mobilize acute intervention, thereby preventing more chronic disability. The idea of an acute stress disorder was initially considered to be superfluous with the diagnosis of adjustment disorder, which was defined in 1980 to describe early symptoms after

any stressful event. The proponents of ASD, however, were interested in emphasizing that, unlike adjustment disorders that were expected to resolve even without treatment, ASD was expected to develop into PTSD. Furthermore, ASD focused on a different set of symptoms that were precursors of PTSD such as dissociation.

Indeed, the symptom of dissociation is a prominent difference between ASD and adjustment disorder. Interestingly, dissociation per se is not a symptom of PTSD. However, there is much support for the idea that if people dissociate at the time of trauma, they are at an increased risk to develop PTSD (Table 1).

Most studies examining the relationship between dissociation at the time of a trauma and development of PTSD have been retrospective, in some studies, assessing the dissociation 25 years after the traumatic experiences. This means that assessment of dissociation is based largely on subjective recollections of victims. However, in studies that have been prospective, peritraumatic dissociation was still found to be one of the best predictors of PTSD 6 months and

Figure 1 Time line comparing ASD and PTSD.

Table 1 Comparison of symptoms of adjustment disorder, ASD, and PTSD

<i>Adjustment disorder</i>	<i>ASD</i>	<i>PTSD</i>
With anxiety	Intrusive reexperiencing	Intrusive reexperiencing
With depression	Avoidance	Avoidance
With mixed anxiety and depression	Hyperarousal	Hyperarousal
With disturbance of conduct		
With mixed disturbance of emotions and conduct	Dissociation Subjective sense of numbing, detachment, or absence of emotional responsiveness A reduction in awareness of his or her surroundings (e.g., being in a daze) Derealization Depersonalization Dissociative amnesia (i.e., inability to recall an important aspect of the trauma)	

1 year following the trauma in a group of mixed civilian trauma. Posttraumatic depression was also a good predictor for the occurrence of PTSD at 1 year. This would perhaps support the idea of including dissociation as a criterion for ASD given its predictive property for the future development of PTSD.

ASD and PTSD are both characterized by the development of intrusive, avoidant, and hyperarousal symptomatology following a traumatic event. These three symptom clusters represent different expressions of the response to trauma.

Intrusive symptoms describe experiences in which the survivor relives the event in their mind. After a traumatic event, it is common for the survivor to have thoughts of the event appear in one's mind and to think about the event despite not wanting to. Frightening thoughts or nightmares about the event are also common, and the person may feel very distressed. Sometimes a survivor may even have physical symptoms such as heart palpitations, sweating, and an increased breathing rate in response to being reminded of the event.

In addition to experiencing one or more of the just-mentioned intrusive symptoms, the survivor may make one or more attempts to avoid being reminded of the traumatic experience. The individual may go out of her way to avoid being in situations that remind her of the event. The individual may forget details about the traumatic event. The survivor may also experience a more generalized feeling of wanting to shut out the world, which is manifested by a feeling of emotional numbness and an inability to connect with others.

Finally, the trauma survivor may experience a range of more physiological symptoms, such as an inability to sleep, inability to concentrate, and anger and irritability. The individual may constantly feel alert and on guard, scanning the environment for signs of danger. The survivor may be very sensitive to noises and have an exaggerated startle response to unexpected or loud sounds. These symptoms are called hyperarousal symptoms.

The conceptualization of ASD remains in evolution at the writing of this volume. The salient question is whether ASD is really a disorder that indicates a deviation from a normative response to stress. To the extent that ASD is a good predictor of PTSD, it may be that this syndrome captures elements of a maladaptive response.

Epidemiology

In considering the prevalence rates of ASD and PTSD, the main observation is that neither are inevitable responses to stress.

The range of prevalence rates of ASD for various types of trauma, including traumatic brain injury (TBI), disasters, and shootings, ranges from 7.2 to 33%, which interestingly are about the same as those for PTSD (see later).

The range of prevalence rates of PTSD in trauma survivors in DSM-IV is 3–58%. This great variation is thought to reflect mostly a difference in the type and quality of the trauma experienced. However, it may also reflect study methodology (i.e., whether people were evaluated in person or on the phone; whether they were selected randomly or from a convenience sample, and/or whether the study was conducted in the immediate aftermath of the trauma or years later). Studies have found that there were differences in the rates of PTSD depending on the type of trauma experienced. For example, 65% of men and 45.9% of women with PTSD reported rape as their most upsetting trauma. Other types of trauma associated with high probabilities of PTSD development include combat exposure (38.8%), childhood neglect (23.9%) and childhood physical abuse (22.3%) in men, and sexual molestation (26.5%), physical attack (21.3%), being threatened by a weapon (32.6%), and childhood physical abuse (48.5%) in women.

In the aggregate, PTSD is estimated to occur on average in 25% of individuals who have been exposed to traumatic events with rates considerably higher for life-threatening events than for those with lower impact. Lifetime prevalence of exposure to at least one traumatic event was also found to range from 40 to 55% in various studies. In the National Comorbidity Survey (NCS), it was found that about 8% of the population were exposed to four or more types of trauma, some of which involved multiple occurrences. The lifetime prevalence of PTSD has consistently been demonstrated to be twice as high in women as in men.

Risk Factors for ASD and PTSD

Risk factors can be divided into two broad categories: those pertinent to the traumatic event (e.g., severity or type of trauma) and those relevant to individuals who experience the event (e.g., gender, prior experiences, personality characteristics). Although some risk factors for PTSD appear to be related to prior experiences, data have also emerged implicating biological and possibly genetic risk factors for PTSD.

Risk factors for the development of ASD include female gender, high depression scores in the immediate aftermath of the event, an avoidant coping style, and the severity of the traumatic event. These are similar to the risk factors that have been associated with the development of chronic PTSD. However, it

should be noted that this has not been an area of extensive study.

Risk factors for PTSD also include female gender, posttraumatic depression, an avoidant coping style, and the severity of trauma. However, additional risk factors have also been noted, such as a history of stress, abuse, or trauma, a history of behavioral or psychological problems, preexisting psychiatric disorders, a family history of psychopathology, genetic factors, subsequent exposure to reactivating environmental factors, initial psychological reaction to trauma such as emotional numbing, early separation, preexisting anxiety and depressive disorders, and depression at the time of trauma. Parental PTSD has also been found to be a risk factor for the development of PTSD.

Comorbid Disorders

PTSD rarely occurs in the absence of other conditions. Approximately 50–90% of individuals with chronic PTSD have a psychiatric comorbidity. This reinforces the idea that PTSD is not distributed randomly throughout the population, but rather that there are subgroups of people that are more vulnerable to the development of PTSD and other psychiatric disorders. This also raises the question of whether PTSD develops as a separate disorder from other psychiatric comorbidities seen in association from it or whether people who have these constellations of disorders are more likely to get PTSD.

Common comorbidities in PTSD patients include major depressive disorder, alcoholism, drug abuse, personality disorders, anxiety disorders such as panic disorder, and generalized anxiety disorder and dissociative disorder.

Symptoms of depression are observed frequently in trauma survivors with PTSD. A significant correlation between early PTSD symptoms and the occurrence of depression seems to predict the chronicity of PTSD. The sequence in which PTSD and major depressive disorder (MDD) occurs following trauma is of particular interest. Some studies proposed that depression is “secondary” to PTSD because its onset followed that of PTSD. In the NCA, patients with comorbid PTSD and MDD reported that the onset of the mood disorder followed that of PTSD in 78.4% of the sample. Vietnam veterans also reported that the onset of their phobias, MDD, and panic disorder followed that of the PTSD. Retrospective studies were flawed in that patients may not recall accurately which symptom came first after being symptomatic for decades. In contrast, Israeli combat veterans reported a simultaneous onset of PTSD and MDD in 65% of the sample, with 16% reported having the MDD precede the PTSD.

In a groundbreaking prospective, longitudinal study, it was demonstrated that the presence of depression in the early aftermath of a trauma was associated with the subsequent development of PTSD. These data contradict the notion that comorbid conditions in PTSD reflect secondary consequences of the PTSD symptoms and suggest instead that other psychiatric symptoms influence the presence of PTSD symptoms. Indeed, a history of previous psychiatric symptoms is a predictor of PTSD, but posttraumatic symptoms may also be strong predictors.

Biological Findings in ASD and PTSD

One of the most provocative observations in both ASD and PTSD that has emerged is that the biological findings do not conform to classic patterns of biological stress responses that have been described in animal and human models of the stress response. This is particularly true in the area of neuroendocrinology of PTSD. The distinctness in the biology of PTSD and stress further supports the idea that PTSD represents a circumscribed and specific response to a traumatic event that may be different from a normative response in which the reaction does not reach a certain magnitude or, if it does, becomes attenuated quickly.

There have been only a few studies of the biology of ASD; however, the biological alterations in ASD seem to resemble those in PTSD. First and foremost, there has been a demonstration of the enhanced negative feedback inhibition of the hypothalamic-pituitary-adrenal (HPA) axis, similar to findings in PTSD (see later). At 2 weeks posttrauma, rape victims who subsequently recovered from ASD at 3 months showed a “normal” response to dexamethasone administration, whereas rape victims who failed to recover from ASD at 3 months showed a hypersuppression of cortisol on the dexamethasone suppression test (DST).

In another study, women with a prior history of rape or assault had significantly lower cortisol levels in the immediate aftermath of rape compared to those who did not. A past history of rape or assault is generally considered to be a potent predictor for the development of PTSD. In a study of motor vehicle accident victims, a lower cortisol response in the immediate aftermath of the trauma was associated with the presence of PTSD at 6 months, whereas higher cortisol levels at the time of the trauma were associated with the development of depression at 6 months. These data indicate that it might be possible to identify high-risk ASD patients through biological means.

In PTSD, there have been far more studies that have yielded fairly consistent results. The studies demonstrate a different profile of HPA alterations in PTSD compared to that in other psychiatric disorders such

as major depression. In the aggregate, these studies have demonstrated a hypersensitization of the HPA axis to stress that is manifested by a decreased cortisol release and an increased negative feedback inhibition. Hypersecretion of the corticotropin-releasing hormone (CRH) has also been described in PTSD, as has blunting of the adrenocorticotrophic hormone (ACTH) response to CRH. Other studies have demonstrated lower 24-h urinary cortisol excretion levels in PTSD patients compared to other psychiatric groups and normal controls. PTSD subjects have also been shown to have lower plasma cortisol levels in the morning and at several time points throughout the circadian cycle and to have a greater circadian signal-to-noise ratio compared to normal controls.

In addition, studies support the notion that the enhanced negative feedback regulation of cortisol is an important feature of PTSD. PTSD subjects have an increased number of lymphocyte glucocorticoid receptors (which are needed for cortisol to exert its effects) compared to psychiatric and nonpsychiatric control groups and show an enhanced suppression of cortisol in response to dexamethasone. This response is distinctly different from that found in depression and other psychiatric disorders.

There have been numerous other systems studies in PTSD such as the sympathetic nervous system, the serotonergic system, and the immune system. Psychophysiological, neuroanatomical, cognitive, and behavioral alterations have also been noted; however, it is beyond the scope of this volume to encompass and discuss all these findings.

Treatment of ASD and PTSD

There are several types of specialized treatments that have been developed in recent years to address the specific needs of trauma survivors who suffer from both ASD and PTSD. These treatments include cognitive behavioral therapy, psychotherapy, group therapy, and medication therapy. Chronic PTSD appears to be more resistant to treatment than acute PTSD. It is usually necessary to employ a combination of therapies in the treatment for PTSD, but the success rate of specialized trauma-focused treatment is quite encouraging.

Summary

ASD and PTSD represent responses that can occur following exposure to traumatic events. To date, it is useful to conceptualize ASD and PTSD as two distinct conditions that are very much related. ASD often but

not always leads to a development of PTSD. ASD and PTSD seem to share similar symptoms, prevalence, risk factors, and neurobiological alterations. ASD appears to be easier to treat than chronic PTSD, which suggests that it is probably useful to treat traumatic stress symptoms earlier rather than later in the course of adaptation to trauma.

Overview of Acute Stress Responses

Stress-Responsive Neuroendocrine Systems

Types of Acute Stressors

Summary and Conclusions

Glossary

<i>Footshock</i>	A laboratory stressor that involves placing a laboratory rat or mouse into a chamber with a floor of metal rods spaced equally apart. Scrambled electric current of known intensity is passed through the metal rods and this results in a mildly painful stimulus to the animal's footpads. This has been a favored stressor in many laboratories because the intensity, duration, and frequency of the footshocks are under the control of the experimenter.
<i>Hemorrhage</i>	An acute decrease in blood volume. In laboratory studies, hemorrhage has been employed as a physiological stressor and blood is often withdrawn via an arterial or venous catheter.
<i>Hypoglycemia</i>	A reduction in blood glucose levels. This physiological change has been employed as a stressor in laboratory studies and insulin is often administered to effect a reduction in blood glucose.
<i>Immobilization</i>	Often employed as a laboratory stressor, immobilization involves restricting the movement of a laboratory animal (typically a rat or mouse) by taping its limbs to padded metal mounts affixed to a frame. A variation on this approach includes restraint, where an animal's movement is restricted by placing it into a plexiglas cylinder.
<i>Neuroendocrine signature</i>	The concept that exposure to a given stressor elicits a pattern of neuroendocrine responses that is specific to that stressor.

Overview of Acute Stress Responses

Humans and animals respond to exposure to a particular stressor by mobilizing a host of neural, neuroendocrine, endocrine, and metabolic systems. Each stressor produces a specific neurochemical signature, with quantitatively if not qualitatively distinct central and peripheral mechanisms involved. These neurochemical changes occur not in isolation but rather in concert with physiological, behavioral, and even experiential changes. In evolutionary terms, natural selection has favored this pattern of coordinated stress responses by enhancing the survival and propagation of genes. This pattern of stress responsiveness is referred to by Goldstein as "primitive specificity." These and other findings are included in the description of acute stress responses that follows.

A stressor may be viewed as a stimulus that disrupts homeostasis. Stressors may be divided into several groups based upon their character, duration, and intensity. Regarding duration, stressors may be characterized as acute (single, intermittent, and time-limited exposure versus continuous exposure) or chronic (intermittent and prolonged exposure versus continuous exposure).

Physical stressors include cold, heat, intense radiation, noise, vibration, and many others. Chemical stressors include ether, all poisons, and insulin. Pain stress may be elicited by many different chemical and physical agents. Psychological stressors profoundly affect emotional processes and may result in behavioral changes such as anxiety, fear, or frustration. Social stressors include an animal's placement into the territory of a dominant animal and in humans unemployment and marital separation among others. Many stressors used in animal research, however, are mixed and act in concert, such as handling, immobilization, anticipation of a painful stimulus, and hemorrhage with hypotension.

In terms of duration, stressors may be divided into two main categories: acute versus chronic stressors. It should be noted that many stressors differ in their intensity. The adaptive responses that are elicited in response to an acute stressor include the physiological and behavioral processes that are essential to reestablish homeostatic balance. During an acute stress response, physiological processes are important to redirect energy utilization among various organs and selectively inhibit or stimulate various organ systems or their components to mobilize energy reserves and to be prepared for exposure to additional, unpredictable challenges. Thus, upon exposure to metabolic

stressors, certain tissues tend to reduce their consumption of energy while others, especially those that are important for locomotor activity, receive sufficient nutrients to function properly. The central nervous system also has priority during metabolic stress responses and preferentially receives a sufficient amount of nutrients from the circulation. The increased supply of energy to crucial organs is achieved preferentially by release of catecholamines and glucocorticoids that in general increase gluconeogenesis and glycogenolysis, inhibit glucose uptake, and enhance proteolysis and lipolysis. The immune system is another essential component of these physiologically adaptive stress responses.

Behavioral adaptation is viewed as a facilitation of adaptive and an inhibition of nonadaptive central and peripheral neural pathways that enable an organism to cope successfully with stressful situations. These behavioral responses include altered cognitive and sensory thresholds, increased alertness, selective memory enhancement, suppression of feeding and reproductive behaviors, and stress-induced analgesia. If physiological or behavioral responses fail to reestablish homeostasis or are excessive and abnormal, diseases of adaptation may be more likely to occur in susceptible individuals. This is apparent upon exposure to chronic or repeated stressors but may happen as well during acute stress reactions in a situation where the intensity of the stressor is abnormally high. Both physiological and behavioral responses are affected by activation of the primary stress effector systems, including the sympathetic nervous system (norepinephrine release), the adrenomedullary system (epinephrine release), the hypothalamic-pituitary-adrenocortical system [adrenocorticotrophic hormone (ACTH) and glucocorticoid release], the parasympathetic nervous system (acetylcholine release), and the renin-angiotensin system (renin release from juxtaglomerular cells in the kidney). Several other systems contribute to a reestablishment of homeostasis, including the hypothalamic-pituitary-thyroid axis (e.g., responsive to cold and heat), the hypothalamic-pituitary-gonadal axis (temporary decrease in reproductive function to shift energy to other more important organ systems), release of growth hormone, and changes in immune function. All of these systems act directly by altering the release or the biological effects of many mediators of acute stress responses (e.g., neurotransmitters, hormones, cytokines, etc.) or they act indirectly by altering levels of monitored variables, with consequent reflexive adjustments determined by internal homeostats.

Stress-Responsive Neuroendocrine Systems

Included below are some examples of ways in which the major stress-responsive physiological systems are altered following exposure to acute stressors.

Hypothalamic-Pituitary-Adrenocortical Axis

The hypothalamic-pituitary-adrenocortical axis is one of the main effector systems that is activated in animals upon exposure to an acute stressor. Generally via several feedback mechanisms at different levels, glucocorticoids released from the adrenal cortex regulate their own synthesis and secretion by actions within the adrenal gland (inhibition of glucocorticoid synthesis), the anterior pituitary (inhibition of corticotrophs), and the hypothalamus [inhibition of corticotropin-releasing hormone (CRH) synthesis and secretion] as well as higher brain centers (e.g., hippocampus). Glucocorticoids readily penetrate the blood-brain barrier and suppress acute stress-induced increases in central neural levels of norepinephrine. Norepinephrine is thought to be the most potent stimulator of CRH neurons within the hypothalamic paraventricular nucleus. Thus, central noradrenergic neurons that terminate in the paraventricular nucleus and synapse on CRH neurons are generally believed to be the site of another negative feedback mechanism by which glucocorticoids attenuate neuroendocrine responses to acute stressors.

During an acute stress response, ACTH and glucocorticoids vary depending on the type and intensity of the stressful stimulus. Exposure of animals to cold stress evokes a very modest increase in plasma ACTH, exposure of animals to hemorrhage or hypoglycemia evokes ACTH responses that reflect the intensity of the stimulus, pain elicits moderate ACTH responses, and immobilization for 120 min evokes the greatest increase in plasma levels of ACTH. The correlation between norepinephrine release in the hypothalamic paraventricular nucleus and plasma ACTH responses may demonstrate the participation of paraventricular norepinephrine in stress-induced activation of the hypothalamic-pituitary-adrenocortical axis ([Figure 1](#)). Although a strong correlation is found between norepinephrine responses in the paraventricular nucleus and plasma ACTH responses during exposure to different stressors, such correlations may not reflect causal interrelationships. During exposure to metabolic stressors such as hypoglycemia or hemorrhage, increments in plasma ACTH are much higher than those of norepinephrine in the

Figure 1 Area under curve measures for microdialysate levels of norepinephrine in the hypothalamic paraventricular nucleus and plasma levels of ACTH from animals exposed to a variety of stressors.

paraventricular nucleus, suggesting that some other paraventricular neurotransmitter or extraparaventricular neuromediators participate in the regulation of the hypothalamic-pituitary-adrenocortical axis following exposure to these stressors. Exposure to pain elicited marked norepinephrine responses in the paraventricular nucleus and moderate plasma ACTH responses, suggesting that paraventricular norepinephrine is responsible for the activation of the hypothalamic-pituitary-adrenocortical axis upon exposure to pain stress. During immobilization stress, the relationship

between paraventricular norepinephrine and plasma ACTH was intermediate, suggesting that both paraventricular norepinephrine and other paraventricular and extraparaventricular neuromediators participate in the regulation of the hypothalamic-pituitary-adrenocortical axis during immobilization stress. Cold stress elicited only minimal paraventricular norepinephrine and plasma ACTH responses, suggesting that other neuroendocrine axes (e.g., thyroid axis) participate in the regulation of homeostasis during acute exposure to cold.

Acute activation of the hypothalamic-pituitary-adrenocortical axis is attended by elevations of plasma glucocorticoids that exert many metabolic effects to mobilize energy necessary for survival of the organism and restoration of homeostasis. Regulatory metabolic effects include gluconeogenesis, glycogenolysis, lipolysis, inhibition of lipogenesis, and proteolysis. Other regulatory effects include anti-inflammatory, anti-allergic, and behavioral effects. Permissive effects of glucocorticoids are important for other hormones or factors to function properly (e.g., catecholamine-induced vascular resistance and cardiac performance are decreased in cases of adrenal insufficiency). Generally, permissive effects of glucocorticoids are responsible for maintenance of a basal or resting state, while regulatory effects are seen when glucocorticoids reach abnormally high concentrations such as when an animal is exposed to an acute and extremely intense stressor.

Hypothalamic-Pituitary-Gonadal Axis

Exposure of animals and humans to acute stress is associated with small and often short-lived increases in plasma luteinizing hormone and androgens. In humans, acute stress-induced increases in androgens appear to be caused by an alteration in plasma volume and a decrease in androgen metabolic clearance rather than from a net increase in androgen release. The mechanisms by which luteinizing hormone is increased under stress conditions are not clear but one possibility is that high levels of ACTH may stimulate gonadotropin hormone-releasing hormone neurons in the hypothalamus. Stress-induced responses are also dependent upon estrogen levels. Thus, in female animals during proestrous or in gonadectomized animals there is no increase in luteinizing hormone upon exposure to acute stress, but instead a rapid decrease in circulating luteinizing hormone may be observed. Norepinephrine and serotonin as well as interleukin-1 also participate in the regulation

of the hypothalamic-pituitary-gonadal axis during acute stress and most likely exert inhibitory effects on gonadotropin-releasing hormone neurons or luteinizing hormone. Follicle-stimulating hormone may follow the same stress response pattern as luteinizing hormone, but often the changes are very small or do not occur at all. The presence of circulating estradiol may provide some protection against the adverse and inhibitory effects of acute stress on the gonadal axis.

In contrast, upon exposure to chronic stress, there are decreases in reproductive function to conserve and redirect energy for other organ systems that are vital for immediate survival. Such inhibition occurs at all levels, including the hypothalamus (inhibition of gonadotropin hormone-releasing hormone secretion), the anterior pituitary (inhibition of luteinizing hormone release), and the gonads (reduced sex hormone secretion). Stress-induced activation of the hypothalamic-pituitary-adrenocortical axis is one of the main factors contributing to this inhibition of gonadal function since corticotropin-releasing hormone and glucocorticoids are known to inhibit gonadotropin hormone-releasing hormone. In addition, glucocorticoids exert inhibitory effects at the level of the anterior pituitary and the gonads.

Sex differences in stress-induced regulation and in responses of primary stress effector systems exist and the presence of circulating estrogen and androgen has been implicated in these differences. It is postulated that estrogens and androgens are responsible for sex hormone-dependent brain organization that reflects differences in responsiveness to stress. For example, estrogen effects on corticotropin-releasing hormone expression may be related to greater stress-induced hypothalamic-pituitary-adrenocortical responses and for a higher incidence of depression, anxiety, and other disorders in human females exposed to stress. In experimental animals, these sex differences are eliminated following surgical removal of the gonads.

Hypothalamic-Pituitary-Growth Axis

It is well documented that acute exposure to various stressors (e.g., hypoglycemia, exercise, hemorrhage, pain) increases secretion of growth hormone from the pituitary gland. In contrast, other stressors such as cold, handling, hypertonic saline, and electric shock produce marked decreases in plasma growth hormone levels. Acute administration of glucocorticoids also increases growth hormone less concentrations in plasma. Thus, it appears that acute stress responses that are associated with elevations in plasma glucocorticoid levels may increase plasma growth hormone levels through stimulation of the growth

hormone gene via glucocorticoid-responsive elements in its promoter region.

In contrast, chronic stress (a state of chronically elevated circulating levels of glucocorticoids) inhibits growth hormone release from the anterior pituitary gland and increases resistance of peripheral tissues to the actions of insulin-like growth factors (e.g., IGF-1). Such inhibition may occur via corticotropin-releasing hormone-induced increases in somatostatin secretion. Thus, dwarfism that occurs in an environment of severe and chronic psychosocial deprivation may reflect a chronically inhibited growth axis.

Little is known about the neural pathways that are involved in stress-induced activation or inhibition of growth hormone secretion. Some evidence suggests that growth hormone responses correlate with changes in catecholamine content in several hypothalamic nuclei, including the paraventricular, dorsomedial, and arcuate nuclei, but more detailed and sophisticated studies are needed to clarify the involvement of catecholamines and other neurotransmitters or neuromodulators in stress-induced growth hormone axis regulation.

Hypothalamic-Pituitary-Thyroid Axis

In contrast to mildly stressful situations, high-intensity stress-induced activation of the hypothalamic-pituitary-adrenocortical axis is associated with inhibition of the thyroid axis. This inhibitory action is reflected by a decrease in release/production of hypothalamic thyrotropin-releasing hormone, decreased production/secretion of thyroid-stimulating hormone, and by inhibition of conversion of thyroxine to the more biologically active triiodothyronine in peripheral tissues. The exception to this pattern is exposure to acute cold stress, forced swimming, or noise stress where profound thyroid axis activation occurs. This is not surprising since during cold exposure, an organism needs to generate significant amounts of energy to maintain body temperature and thyroid hormones are known to increase heat production and therefore core temperature. Upon exposure to cold stress, there is increased secretion of hypothalamic thyrotropin-releasing hormone, which leads to increases in release of thyroxine within 15–20 min and triiodothyronine within 1–2 h. The mechanism by which cold-induced activation of thyrotropin-releasing hormone occurs is not fully understood, although catecholamines are thought to participate in this process. It is well known that in a hypothyroid state, plasma catecholamines are elevated and during a hyperthyroid state plasma catecholamines are either unchanged or decreased. In thyroidectomized rats, larger increments in plasma epinephrine and norepinephrine occur during cold

exposure, suggesting compensatory activation of catecholamine secretion as a result of the loss of the thyroid gland. The organism is faced with difficulty in maintaining body temperature when the hypothalamic-pituitary-thyroid axis is unable to enhance thermogenesis.

The reason that the thyroid axis is inhibited upon exposure to other stressors is unknown but one possible explanation is that an organism conserves energy necessary for survival and restoration of homeostasis. Corticotropin-releasing hormone, somatostatin, and cytokines (e.g., IL-1 and IL-6) most likely contribute to acute stress-induced inhibition of the thyroid axis.

Prolactin

Prolactin is another anterior pituitary hormone that is increased during exposure of animals to various stressors such as exercise, hypoglycemia, hemorrhage, immobilization, and pain stress. Other situations associated with elevated plasma prolactin levels are nipple stimulation during lactation, chest wall lesions (herpes, incisions), and the acute stress of blood withdrawal. The mechanisms by which acute stressors increase prolactin secretion remain unknown. The physiological consequences of prolactin hypersecretion during stress are not clear, although it is hypothesized that prolactin enhances immune function.

Immune System

The immune system is an important component of acute stress responses although interactions between immune system components and other stress effector systems are very complex and still poorly understood. Upon exposure to various acute stressors, inflammatory cytokines such as tumor necrosis factor and interleukin (IL)-1 and -6 are increased. These substances participate in the maintenance of immunologic homeostasis as well as in regulation of the hypothalamic-pituitary-adrenocortical axis. Interleukin-6 appears to be a very potent stimulator of the hypothalamic-pituitary-adrenocortical axis that most likely occurs via activation of paraventricular CRH neurons. Neuronal pathways participating in interleukin-induced CRH activation are still not well characterized. Stress-induced elevated plasma glucocorticoid levels in turn have profound inhibitory effects on various immune functions. For example, production of cytokines, mediators of inflammation, leukocyte function and traffic, cell-mediated immunity, and suppressor T-cell function are all decreased by stress-induced elevations in glucocorticoid levels.

Immunosuppressive and anti-inflammatory effects of glucocorticoids are essential to prevent harmful

infections or unwanted exaggerated immune reactions so as to increase chances for survival. This is well-documented from studies where Lewis rats that are characterized by hyporesponsiveness of the hypothalamic-pituitary-adrenocortical axis (deficient CRH neurons?) have increased susceptibility to inflammatory diseases upon exposure to a variety of stressful stimuli.

Autonomic Nervous System

The sympathoneuronal and adrenomedullary systems are two major stress effector systems. Numerous recent studies have demonstrated differential responses of these two effector systems during exposure to various stressors. In several recent studies, an attempt was made to measure simultaneously release of norepinephrine in the hypothalamic paraventricular nucleus (the most important area in the regulation of the hypothalamic-pituitary-adrenocortical axis and the site where noradrenergic neurons synapse on CRH neurons) using *in vivo* microdialysis and plasma levels of catecholamines and ACTH. These multiple neuroendocrine measures provided an answer to whether stressor-specific noradrenergic activation of the hypothalamic-pituitary-adrenocortical axis and stressor-specific responses of sympathoadrenal and adrenomedullary systems occur. During exposure to any of several stressors, there was a significant correlation between plasma levels of ACTH and paraventricular microdialysate levels of norepinephrine. Although for all stressors levels of norepinephrine in the paraventricular nucleus correlated significantly with plasma ACTH levels, detailed examination of these variables showed differences and not necessarily causal interrelationships. During exposure to metabolic stressors, such as hypoglycemia and hemorrhage, increments of plasma ACTH were much larger than those of norepinephrine in the paraventricular nucleus, suggesting that ACTH release can occur by pathways other than activation of noradrenergic neurons terminating in the paraventricular nucleus. Other intra- or extra-paraventricular non-adrenergic neurons are most likely responsible for stimulating ACTH release during these stressors. In response to pain stress, relatively small ACTH responses were associated with large increases in paraventricular norepinephrine release, suggesting that norepinephrine in this brain region could be a stimulator of CRH neurons. The slope of the relationship between paraventricular norepinephrine release and plasma ACTH responses was intermediate during immobilization stress, suggesting that both noradrenergic and nonadrenergic neurons participate in the regulation of the hypothalamic-pituitary-adrenocortical axis.

Table 1 Selected behavioral and physiological adaptations designed to restore homeostasis during acute exposure to stressful stimulation

<i>Behavioral adaptation</i>	<i>Physiological adaptation</i>
Increased arousal and alertness	Oxygen redirection to CNS and stress-activated tissues
Euphoria or dysphoria	Nutrients redirected to CNS and stress-activated tissues
Suppression of appetite or feeding behavior	Increased blood pressure and heart rate
Suppression of reproductive behavior	Increased respiratory rate
	Increased gluconeogenesis, glycogenolysis, and lipolysis
	Detoxification of endogenous or exogenous toxic products
	Inhibition of reproductive system
	Inhibition of colonic motility

in response to the combined psychological and physical stress of immobilization.

These and other findings can be applied to a new concept of stressor-specific neurocircuits in brain and neuroendocrine signatures that are related to specific stressors. The recognition and description of stressor-specific neurocircuits, including mapping of neurotransmitters participating in these neurocircuits, may lead to the development of new therapies for stress-related disorders.

Types of Acute Stressors

Included below are descriptions of the responses to some of the acute stressors that have been employed frequently in laboratory animal studies of stressful stimulation. In the majority of these studies, the focus of attention was directed at the sympathetic-adrenal medullary system or the hypothalamic-pituitary-adrenocortical system. In the former, measures of plasma levels of norepinephrine and epinephrine were reported and in the latter plasma levels of ACTH and/or corticosterone were made.

Hypoglycemia

Hypoglycemia is characterized by a fall in plasma glucose levels under various conditions, including starvation, hepatic dysfunction, administration of insulin, pancreatic B cell tumor, alcohol use, and adrenal insufficiency. Acute decreases in blood glucose levels are associated with increases in circulating levels of epinephrine, ACTH, and cortisol, with little if any concurrent sympathoneuronal system activation as indicated by circulating norepinephrine levels. The selective adrenomedullary activation during

hypoglycemia constitutes key evidence for the differential regulation of stress effector systems. Hypoglycemia is characterized by many symptoms associated with neuroglycopenia, including tremulousness, sweating, hunger, palpitations, anxiety, psychotic behavior, seizures, and coma.

The central neuronal circuitry responsible for the elicitation of hunger and eating in response to hypoglycemia remains poorly understood. Stimulation of catecholamine release by insulin-induced hypoglycemia is thought to involve both neurogenic and nonneurogenic mechanisms. Neurogenic mechanisms participate in the initial acute phase (the first 30 min after insulin administration) in which plasma epinephrine levels increase but plasma norepinephrine levels remain unchanged. Glucose-sensitive receptors in the hypothalamus and preganglionic cholinergic nerves that innervate the adrenal medulla are involved in this phase when an absolute fall in plasma glucose levels rather than actual hypoglycemia is an important mechanism to trigger catecholamine responses. Nonneurogenic mechanisms participate in the second phase (30–50 min after insulin administration) and produce increases in both plasma epinephrine and norepinephrine. These responses are independent of a functionally intact nerve supply to the adrenal medulla and can be reversed by glucose administration, suggesting that hypoglycemia is the mechanism that triggers catecholamine responses. However, it should be mentioned that several other studies have not found a biphasic pattern of hypoglycemia-induced catecholamine responses, which may be explained by differing experimental conditions, including the severity of hypoglycemia.

Hemorrhage

Depending upon whether hypotensive or nonhypotensive hemorrhage occurs, various physiological responses are elicited, including activation of the hypothalamic-pituitary-adrenocortical axis, increased vasopressin release, and elevated plasma catecholamine levels. Similar to hypoglycemia, hemorrhage elicits relatively small increases in paraventricular levels of norepinephrine. Activation of all of these systems is an important counterregulatory mechanism to maintain homeostasis.

In clinical studies, acute hypotensive hemorrhage is an extremely dangerous situation since it may lead to shock. Acute hemorrhagic shock is characterized by an activation of all of the main stress effector systems. Clinical symptoms of the former include low energy level, fatigue, a feeling of being cold, dizziness, and sleepiness; clinical signs of the latter include cool or mottled extremities, increased heart rate, low blood pressure, pallor, and altered mental status, ranging

from restlessness and agitation to coma. Restoration of blood volume is a high priority, although fluid replacement that is too rapid may be harmful since it may shut down the level of activity of the sympathoadrenal system in the critical period when survival depends on the activity of these stress effector systems.

Hypoxia

Asphyxiation produces the biochemical triad of hypoxemia, hypercarbia, and acute respiratory acidosis. Chemoreceptors, located especially in the carotid bodies adjacent to the carotid sinuses, respond to decreased arterial oxygen concentrations, increased arterial carbon dioxide concentrations, and decreased arterial blood pH. Chemosensitive cells near the ventral surface of the medulla respond to these same stimuli. Acute exposure to hypoxemia and hypercarbic acidosis is associated with increased or unchanged plasma levels of norepinephrine and epinephrine and with increased sympathetic nerve traffic as measured by microneurography. Findings of unchanged plasma norepinephrine levels during acute hypoxemia may be explained by increased nor-epinephrine clearance. The activation of sympathoneuronal and adrenomedullary systems is associated with increases in heart rate, respiration, and vasoconstriction. Sympathectomy decreases and adrenalectomy eliminates increases in heart rate and cardiac output that result from severe hypoxia.

Acute mountain sickness caused by sudden exposure to hypoxia is a frequent cause of morbidity and mortality in people who travel to high altitudes. It is estimated that 30 million people are at risk for altitude-related diseases in the western United States every year. Approximately 20% of tourists who travel to ski resorts in Colorado experience acute mountain sickness. Symptoms of acute mountain sickness include headache, nausea, anorexia, insomnia, cough, difficulties in physical activity, mental changes, seizures, hallucinations, and, finally, in severe cases, coma. All of these symptoms may occur suddenly after a few hours in a high-altitude environment and require immediate medical attention.

Pain

Following exposure of laboratory animals to acute pain induced by formalin administration, only small increments in plasma ACTH levels occur despite large increments in plasma norepinephrine and epinephrine levels. Brainstem centers are the recipients of ascending pathways carrying nociceptive information and are perhaps the most important brain areas in pain mechanisms. Glutamate, aspartate, substance P, and

calcitonin gene-related peptide are neurotransmitters that participate in acute pain responses. It is known that behavioral analgesia or inhibition of spinal neurons that respond to painful stimuli may be eliminated by electric stimulation or opiate microinjection into several brainstem regions.

Cold

Cold exposure has been employed as a stressful stimulus in laboratory studies. Several experimental approaches have been taken in these studies. In one such approach, animals are placed in their home cages in a cold environment maintained at a constant temperature and remain there for varying periods of time. Typically the stress session can extend from several hours to multiple days. Alternatively, animals are immersed in water at a given temperature for less than an hour. Exposure to a cold environment at or below 0°C results in dramatic increases in plasma norepinephrine but only modest increases in plasma levels of epinephrine and ACTH. In contrast, placement of laboratory rats in cold water (20–25°C) for as little as 15 min is attended by substantial increases in plasma levels of epinephrine and norepinephrine. The increases in plasma levels of both catecholamines in response to cold swim stress are negatively correlated with water temperature over the range of 20–34°C, with the highest levels of plasma catecholamines at the lowest water temperatures. Indeed, plasma levels of epinephrine during swim stress at 18–20°C are among the highest ever measured for a laboratory stressor.

Footshock

Footshock has been especially valuable as a stressor in studies of neural and endocrine responsiveness. Footshock allows investigators exquisite control over the frequency, intensity, and duration of the stressful stimulus. In addition, footshock is often employed as an aversive stimulus in studies of learning and memory, allowing for studies that link physiological and behavioral responses. Footshock stress activates the sympathetic-adrenal medullary and hypothalamic-pituitary-adrenocortical systems, especially at moderate to high intensity footshock levels (1–2 mA).

Immobilization

For more than 30 years, Kvetnansky and his colleagues have employed immobilization as a consistent feature of their studies on physiological adaptations to stress. Immobilization is a potent stressor and includes physical as well as psychological dimensions. Typically,

laboratory rats are fixed to a holder by taping their limbs to padded metal mounts. The stress sessions usually last from 30 to 120 min and may be repeated each day for up to 1 month to assess responses to acute versus repeated stress. A single session of immobilization results in extremely high levels of circulating norepinephrine, epinephrine, ACTH, and corticosterone when compared to other laboratory stressors. Levels of norepinephrine, epinephrine, and ACTH usually peak within the first 30 min of immobilization and then decrease to a stable but highly elevated level for the remainder of the stress session. In contrast, plasma levels of corticosterone peak later in the stress session and remain high for the remainder of the period of immobilization.

Summary and Conclusions

Since its inception, the field of stress research has lacked a strong theoretical foundation upon which investigators could formulate questions, design experiments, and interpret their findings and the work of others. From the beginning of his career, Hans Selye offered a definition of stress that was all encompassing and he advanced a view that exposure to any stressor results in a consistent pattern of physiological responses. Although these concepts are no longer at the forefront of stress research, they have left an indelible imprint.

In the absence of a strong theoretical foundation, much of the effort in the field of stress research has been linked to the development of techniques for measuring biologically active molecules or visualizing substances within various tissues, especially neural tissue. The nature of the stressor in a given study was for a time almost an afterthought. Thus, many laboratories developed their own unique stressors and focused much of their creative energies on assay methodologies. Without a set of consistent stress paradigms, comparisons of research results across laboratories were difficult.

In this overview of acute stress responses, we have provided a brief background on the major stress-responsive neuroendocrine systems. Then we examined the pattern of neuroendocrine responses across some of the commonly used laboratory stressors. After distilling the results of thousands of studies of neuroendocrine activation during acute stress, the case for specificity of physiological responses to different stressors is overwhelming. These neuroendocrine signatures allow an animal to respond to a given stressor with an optimal recruitment of physiological responses

to meet the immediate demands of the situation. It is important to keep in mind that most acute stress paradigms present the subject with a great deal of uncertainty and loss of control. The subject has never experienced the stressor before and has no knowledge of how long the stressor will persist, if escape is possible, if stressor intensity will remain constant, and so on. These psychological variables affect central neural circuits that coordinate neural and endocrine activation and must be considered in interpreting the findings of a given acute stress experiment.

Neuroendocrine Response to Injury
Immune Response to Injury
Metabolic Response to Injury
Interactions of the Biological Responses
Therapy and Modification of Responses

Glossary

<i>Apoptosis</i>	Programmed cell death; deletion of cells by fragmentation into membrane-bound particles that are phagocytosed by other cells.
<i>Cytokine</i>	A protein that acts as an intercellular mediator in the generation of the immune response.
<i>Glucocorticoids</i>	A class of steroid hormones, secreted by the adrenal cortex, that influence intermediary metabolism and exert an anti-inflammatory effect.
<i>Reflex</i>	A reaction in response to a stimulus applied to the periphery and transmitted to the nervous centers in the brain or spinal cord.
<i>Sodium pump</i>	Sodium-potassium adenosine triphosphatase, an enzyme responsible for maintaining the sodium and potassium electrical gradient between the intracellular and interstitial compartments.

The acute trauma response to injury encompasses a complex interplay of multiple host homeostatic processes. Although the overall response to trauma is most easily conceptualized by considering the individual components of the neuroendocrine, metabolic, and immune systems, it is important to recognize that many molecular, cellular, humoral, and physiological mechanisms and cascades develop interactively. The ultimate ability of the injured patient to recover from the insult depends on the dynamic relationship between this host response and timely medical or surgical intervention ([Figure 1](#)).

Neuroendocrine Response to Injury

The classic neuroendocrine reflex is comprised of afferent stimuli, central nervous system integration and modulation, and efferent output. Following traumatic injury, multiple discrete chemical and physiological perturbations are detected by specific sensors. After local transduction of stimuli, these signals are transmitted to the central nervous system via specific neural pathways and directed to highly specialized cellular nuclei for processing and integration with other signals. The resultant efferent output is the secretion of various hormonal substances by individual organ systems. Modulation of the intensity and pattern of release of these hormones is affected by short reflex arcs and long regulatory feedback loops, whether stimulatory or inhibitory.

Afferent Input

After a severe injury, tissue destruction and hemorrhage appear to be two of the most important early alterations. From the site of injury, peripheral sensory receptors of primary nociceptive afferent neurons detect mechanical deformation and thermal changes. Damaged cells release chemicals, such as histamine, potassium, serotonin, thrombin, and others, which also provide nociceptive input. The cell bodies of these neurons reside in the dorsal root ganglia and transmit signals to the spinal dorsal horn, where secondary neurons and collateral pathways project to tertiary neurons in the brain stem and thalamus.

Hypovolemia is the most common cause of circulatory shock after injury. Significant blood loss leads to a decrease in effective circulating volume and blood pressure. Tissue injury and fluid sequestration may contribute to hypovolemia. These changes are sensed by pressure-sensitive baroreceptors in the aorta and carotid arteries and volume-sensitive stretch receptors in the atria and vena cava. Fibers from these primary neurons ascend in the vagus nerve to the nucleus of the solitary tract. Secondary neurons project to the medullary reticular formation and cardiovascular pressor and depressor areas of the brain stem.

Many other alterations, including fear and anxiety or changes in oxygen concentration, temperature, and energy substrates, provide afferent input to the neuroendocrine system. The perception of danger or threat of injury stimulates the central limbic system with fiber projections to the hypothalamus. Optic, olfactory, or auditory information may provide substantial

Figure 1 Schematic diagram depicting the interactions of the neuroendocrine, immune, and metabolic systems after traumatic injury. Processing and integration of multiple stimuli, and modulation through the interactions of various mediators, form the overall biological response. Modification of this response by therapeutic interventions facilitates achieving and maintaining homeostasis.

signals. Injuries that affect airway, breathing, or circulation may result in hypoxia, hypercarbia, or acidosis. Chemoreceptors located in the carotid and aortic bodies and in the central nervous system detect decreases in the plasma concentration of oxygen and increases in the concentration of carbon dioxide or hydrogen ions. Fibers from these neurons project to both the cardiovascular and respiratory centers of the medulla. Hemorrhage and exposure after trauma leading to hypothermia and core temperature changes are sensed in the hypothalamic preoptic area.

Integration and Modulation

Multiple signals from different pathways are modulated at several levels. The primary input depends on the nature, intensity, and duration of the stimulus. Sequential or repetitive stimulation, as well as the status and responsiveness of the receptor, all influence the response. The sensory signal arrives at the medullary center for integration with other ascending signals, interneurons, and descending inhibitory inputs. The various signals from nociceptors, baroreceptors, chemoreceptors, somatosensory afferents, and limbic system project from the brain stem nuclei to converge at the hypothalamus.

Efferent Output

Pituitary regulation There are two main components to the efferent limb of the neuroendocrine response: hormones under hypothalamic-pituitary axis control and hormones under autonomic nervous

system control. The hypothalamic-pituitary-adrenal (HPA) axis has been extensively studied and represents a model neuroendocrine response system to stress. Although corticotropin-releasing hormone (CRH), adrenocorticotropic hormone (ACTH), and cortisol are secreted sequentially, the fine control of the system is achieved through neural integration, feedback loop regulation, and intermediary substances. Multiple inputs are integrated at the hypothalamic paraventricular nucleus (PVN) to generate the efferent arc.

CRH is the primary stimulant of the synthesis and secretion of ACTH by corticotrophs in the anterior pituitary gland. ACTH is released as a cleavage product of proopiomelanocortin and subsequently acts to stimulate the synthesis and release of glucocorticoids from the adrenal cortex.

Cortisol is the primary glucocorticoid in the response to stress and has widespread effects on host metabolism. Among its many metabolic actions are potentiation of glucagon and epinephrine leading to hyperglycemia, stimulation of gluconeogenesis in the liver, stimulation of amino acid release in skeletal muscle leading to proteolysis, and increase in lipolysis and fatty acid release. Cortisol is also essential in the compensatory hyperosmolar response necessary to achieve complete blood volume restitution. The magnitude of injury influences the intensity of the CRH-ACTH-cortisol response.

While earlier hemorrhage potentiates the ACTH response, circadian factors may mask this effect. Along with the elevation in plasma cortisol levels, the normal diurnal variation is lost. This altered

pattern of adrenal cortisol secretion is associated with a similar loss of diurnal variation in both ACTH secretion and the adrenocortical sensitivity to ACTH stimulation. In pure hypovolemia, plasma cortisol levels rapidly normalize when blood volume has been restored. Persistently elevated cortisol suggests ongoing stimulation from tissue hypoxia or supervening infection and is associated with reduced survival.

Hypothalamic thyrotropin-releasing hormone (TRH) stimulates the release of thyroid-stimulating hormone (TSH) from the anterior pituitary. TSH is responsible for the release of primarily thyroxine (T_4) from the thyroid gland, which is converted to triiodothyronine (T_3) peripherally. Thyroid hormones also have multiple metabolic effects, the most important of which are increases in oxygen consumption and heat production. After injury, peripheral conversion of T_4 to T_3 is impaired and there is no compensatory rise in TSH release.

The role of the endogenous opioids after injury and hemorrhage is an area undergoing active investigation. The opioids, including the endorphins and enkephalins, are secreted by cells in the central nervous system, intestinal wall, and adrenal medulla. They act upon various receptors to produce different effects. In the central nervous system, opioid peptides act as neurotransmitters to attenuate pain by inhibiting nociception. The excess release of endogenous opioid peptides has been linked to the cardiovascular collapse of shock. One suggested mechanism for opioid-induced hypotension after acute hemorrhage is a decrease in sympathetic outflow, mediated by serotonergic pathways. After hemorrhagic or septic shock, the administration of the opiate receptor antagonist naloxone has been shown to improve cardiovascular function, systemic blood pressure, and survival time.

Growth hormone (GH), gonadotropins, and prolactin are other anterior pituitary hormones involved in the neuroendocrine response. GH promotes protein synthesis and is elevated following injury. Gonadotropin-releasing hormone (GnRH) stimulates the release of follicle-stimulating hormone (FSH) and luteinizing hormone (LH), both of which are suppressed after injury. Although the hypothalamus exerts tonic suppression of pituitary prolactin release, elevated levels have been reported after injury in adults.

Arginine vasopressin (AVP), or antidiuretic hormone, is synthesized in the hypothalamus and transported to the posterior pituitary gland for storage. Secretion of AVP is increased immediately after injury. Stimuli for AVP release include increased plasma osmolality and changes in effective circulating volume. Actions of AVP include reabsorption of free water in the renal distal tubules and collecting ducts,

peripheral and splanchnic vasoconstriction, and hepatic glycogenolysis and gluconeogenesis.

Autonomic regulation The catecholamines are essential components of the physiological response to injury. Norepinephrine is primarily released from the axon terminals of postganglionic neurons with subsequent overflow into plasma. The rate of norepinephrine release correlates with the intensity of sympathetic nervous system activity. Epinephrine is directly secreted into the circulation from stimulation of the adrenal medulla. Like other hormones, the catecholamines exert both hemodynamic and metabolic actions, including enhanced cardiovascular function, vasoconstriction, hepatic glycogenolysis and gluconeogenesis, and peripheral lipolysis.

The renin-angiotensin-aldosterone system serves to maintain intravascular volume. Renin catalyzes the conversion of angiotensinogen to angiotensin I within the kidney, which in turn is converted into angiotensin II in the pulmonary circulation. Angiotensin II and ACTH are stimuli for the secretion of aldosterone from the adrenal cortex. The predominant action of aldosterone is enhancement of the Na^+/K^+ -ATPase enzyme in the renal distal convoluted tubules and collecting ducts to increase reabsorption of sodium and elimination of potassium.

Insulin and glucagon play opposing roles in the maintenance of substrate homeostasis. Insulin is the primary anabolic hormone and promotes the storage of carbohydrate, protein, and lipid. After injury, sympathetic nervous system activity inhibits insulin secretion from pancreatic beta islet cells and cortisol inhibits glucose uptake with the net result of hyperglycemia and catabolism. Glucagon is synthesized in the pancreatic alpha islet cells and increases protein and lipid catabolism by increasing hepatic glycogenolysis and gluconeogenesis.

Immune Response to Injury

Immune cells and inflammatory mediators activated by tissue injury are important components in the response to trauma. Among the substances released by activated inflammatory cells are cytokines, endothelial cell factors, and eicosanoids. The actions of these varied mediators in hemorrhage, sepsis, and injury have been the subject of intense investigation.

Cytokines

Cytokines are a class of small proteins produced by the full range of inflammatory cells. They are active at low concentrations and may have paracrine, autocrine, or endocrine effects. Cytokines regulate the production of immune cells and other cytokines by

either potentiating or attenuating the inflammatory response.

Manifestations of cytokine response include fever and alterations in cardiovascular and respiratory function. Excessive cytokine release has been implicated in the ongoing inflammation and injury associated with sepsis and multiple organ failure. The number of cytokines involved is too numerous to list here, but the best characterized include the interleukins (ILs), tumor necrosis factor- α (TNF- α), the interferons, and granulocyte/macrophage-colony stimulating factor (GM-CSF).

After injury, TNF- α , or cachectin, is one of the earliest cytokines released by monocytes, macrophages, T cells, and endothelial cells. TNF- α has been shown to act synergistically with IL-1 to induce hypotension, tissue injury, and death in animals. Its metabolic effects include proteolysis in skeletal muscle and hepatic gluconeogenesis.

The interleukins are a family of cytokines also derived from monocytes, macrophages, T cells, and endothelial cells. The best characterized of these cytokines in trauma is IL-1. The two species IL-1 α and IL-1 β have differential actions, but IL-1 β is believed to be more biologically relevant. Among its many systemic effects are mediating fever by stimulating the synthesis of E series prostaglandins in the thermoregulatory center of the hypothalamus, promoting synthesis of hepatic acute phase proteins, and promoting skeletal muscle proteolysis.

Interferon- γ is a glycoprotein released by stimulated helper T cells. It activates circulating and tissue macrophages to release TNF- α and other interleukins. GM-CSF is a growth factor cytokine that plays a prominent role in wound healing after injury. It augments maturation of functional leukocytes and delays the apoptosis of immune cells.

Endothelial Cell Mediators

Endothelial cell-derived substances have predominantly local actions of vasomotor regulation and modulation of coagulation, but may have additional systemic effects on cardiovascular and neuroendocrine systems, as well as cytokine stimulation. Nitric oxide (NO) was formerly known as endothelium-derived relaxing factor. It has been shown that a basal release of NO induces a tonic state of arteriolar vasodilatation. Cellular injury, endotoxin, and hypoxia stimulate increased release of NO, and its effects are primarily exacerbation of the vasodilatory state. Conversely, the endothelins exert potent vasoconstrictor properties. Endothelin-1 is the most biologically active member of this family and is estimated to have 10 times more vasoconstrictor potency than angiotensin II. Increased serum levels of endothelin-1

correlate with the severity of injury. Platelet-activating factor stimulates production of thromboxane (TXA₂) and promotes platelet aggregation. Its actions include increasing vascular permeability by altering the shape of endothelial cells.

Eicosanoids

The eicosanoids are phospholipid mediators derived from arachidonic acid through the action of phospholipase A and include the prostaglandins, thromboxanes, and leukotrienes. Actions of prostaglandins and prostacyclin include increased vascular permeability, leukocyte migration, and vasodilation. TXA₂ is synthesized in platelets, acts as a potent vasoconstrictor, and promotes platelet aggregation. The leukotrienes mediate anaphylaxis by promoting capillary leakage, bronchoconstriction, and vasoconstriction.

Metabolic Response to Injury

Substrate Metabolism

Altered substrate metabolism after injury is often compared and contrasted with that during fasting. The adaptive responses to fasting of decreased substrate utilization and decreased metabolic rate are modified by the stress responses to pain, tissue damage, hemorrhage, and inflammation. The early phase is characterized by generalized catabolism, protein wasting, negative nitrogen balance, and hyperglycemia. Fever, increased myocardial work, and early wound healing all increase energy expenditure and metabolic rate. After existing hepatic glycogen stores are depleted, lipids become the primary source of fuel. Lipolysis is enhanced by catecholamines, cortisol, and glucagon. Despite increased insulin secretion, hyperglycemia results from increased hepatic glycogenolysis and gluconeogenesis, mediated by cortisol and catecholamines, and in the periphery, from inhibition of insulin-mediated glucose uptake.

The increased urinary excretion of nitrogen reflects net proteolysis. The severity of injury correlates with the degree of total body protein turnover. Following trauma, the major source of amino acids is skeletal muscle, the primary carriers of nitrogen being alanine and glutamine. Although the total amino acid concentration is unchanged, changes in alanine and glutamine synthesis and release depend on the extent of overall injury and oxygen consumption.

Electrolyte Metabolism

Decreased effective circulating volume is exacerbated by tissue damage and obligatory sequestration of fluid into extravascular compartments. After trauma, not only is there interstitial accumulation of fluid from the capillary leak of injured and inflamed tissue,

but there is also mobilization of salt and water into the intracellular compartment. Previous studies have shown that the cellular membrane sodium-potassium adenosine triphosphatase (Na^+ , K^+ -ATPase), or sodium pump, is impaired in shock leading to muscle cell membrane depolarization. An influx of sodium and chloride ions, followed by water, results in cell swelling and further depletion of extracellular volume, and may lead to irreversible shock.

The renal conservation of salt and water may also be affected by increased glomerular filtration fraction, increased proximal reabsorption of sodium, and increased blood flow to juxtamedullary nephrons through aldosterone and glucocorticoid effects. Increased levels of AVP contribute to water retention and may manifest as oliguria. In the presence of hypovolemia or hypotension, there is increased risk of acute tubular necrosis. Adequate resuscitation with balanced salt solutions helps to maintain medullary osmolar gradient and tubular fluid flow.

Interactions of the Biological Responses

Although the effects of individual hormonal and immune substances have been well characterized, their interrelationships in the overall biological response have yet to be well elucidated. Multiple stimuli certainly interact and converge in the central nervous system. This concept is supported by studies demonstrating potentiated responses of ACTH to hemorrhage after simultaneous or repetitive application of subthreshold stimuli.

One focus of interest has been the interactions of immune mediators with the HPA system. Impaired host wound healing and decreased resistance to infection in some critically injured patients have popularized the concept of injury-induced immunosuppression. Although it is known that pharmacological doses of corticosteroids produce immunosuppression, it is unclear whether the physiological increase in endogenous cortisol directly causes immunosuppression. Instead, the immune dysfunction after injury may also be mediated by the stimulation of the autonomic nervous system or other hormones.

There is evidence that IL-1 may activate the HPA axis by a central action on the hypothalamus. IL-1 increases the release of CRH from isolated rat hypothalamus, and other studies have shown that IL-1-stimulated ACTH release is associated with decreased CRH content in the median eminence. Other investigators have reported increased levels of circulating ACTH and corticosterone in rats after intravenous injection of IL-1.

It is still unclear whether IL-1 has a direct or indirect effect on the HPA axis. There is some evidence that these actions of IL-1 may be mediated by

prostaglandins. Microinjections of prostaglandin antagonist into the preoptic area block the ACTH response to intravenous IL-1 β . In addition, the effect of IL-1 β on ACTH release may not be a result of changes in CRH. Reports have suggested that IL-1 β stimulates norepinephrine and dopamine release in the hypothalamus and that the ACTH response to IL-1 injection in the median eminence can be blocked by adrenergic antagonists. Similarly, both IL-6 and TNF- α have also been associated with increased levels of circulating ACTH. Like IL-1, this stimulatory effect may also be related to activation of the HPA system through a prostaglandin-mediated increase in CRH release.

Studies have documented the immunosuppressive effects of androgens, citing differences between male and female immune function. Androgen-deficient mice have enhanced IL-2 and interferon- γ production by peripheral T cells. In addition, it has been shown that castrated male mice subjected to soft tissue trauma and hemorrhage had elevated plasma corticosterone levels and splenocyte proliferation compared to sham animals.

Local production of various hormones from immune cells may lead to paracrine effects. Lymphocytes have been shown to produce ACTH, a TSH-like peptide, and a GH-like peptide, among others. Immune cells also possess various hormone receptors. Receptors for CRH, TRH, growth hormone releasing hormone, ACTH, and opioids have been found on leukocytes. These findings certainly point to a communication between the immune and neuroendocrine systems. Considerably more research is needed to further understand these complex interactions.

Therapy and Modification of Responses

Fluid Resuscitation

Initial management after severe injury involves control of hemorrhage, administration of intravenous isotonic crystalloid fluids, and blood transfusion, if needed, which immediately improves effective circulating volume. The replenishment of intravascular volume results in an increase in capillary hydrostatic pressure, reversing the flux of water out of the interstitial compartment. Reflex sympathetic vasoconstriction and catecholamine release are diminished as increased blood pressure is sensed by baroreceptors. The result is improved capillary perfusion and organ function, and the prevention of the adverse consequences of tissue ischemia and cellular hypoxia.

Recent evidence suggests that when severe hemorrhage accompanies trauma, delaying intravenous fluid resuscitation until bleeding is controlled can reduce morbidity and mortality. Aggressive and rapid fluid resuscitation may accentuate blood loss

when hemorrhage is not yet controlled. Furthermore, rapid fluid resuscitation may accelerate reperfusion organ injury so that sufficient fluid should be infused at only a moderate rate to restore optimal intravascular volume.

Pain Management

Administration of narcotic analgesics provides pain control, reduces sympathetic nervous system activity, reduces the release of endogenous opioids, and decreases cortical and limbic inputs. Studies have shown that preoperative administration of morphine diminishes the usual rise in plasma ACTH, cortisol, GH, and glucose. Furthermore, studies have shown that denervation of the wound or regional anesthesia ablates afferent signals and suppresses adrenal stimulation.

Local Wound Care

Tissue damage induces the local release of cytokines, immune complexes, and complement split products from phagocytes and lymphocytes. An exaggerated local inflammatory response from the wound may amplify and cause adverse systemic effects. Therefore, early removal of debris and debridement of devitalized tissues will attenuate this inflammation. Stabilization of fractured limbs prevents repetitive soft tissue trauma, and fasciotomy relieves compartment syndrome to improve tissue perfusion.

Intensive Care Unit Admission

One of the goals of resuscitation is to restore and maintain optimal perfusion and prevent tissue ischemia. Vasomotor changes, myocardial dysfunction, shock, hypothermia, and respiratory insufficiency all contribute to the difficulty of gauging the adequacy of therapy without intensive care unit (ICU) admission. In an ICU environment, all physiological functions may be closely monitored for evidence of deterioration and to assess response to therapy. A pulmonary artery catheter allows the monitoring of cardiac filling pressures and cardiac output. Systemic oxygen delivery and consumption estimates can be derived from these measurements to facilitate resuscitation.

Nutritional Support

Most victims of mild injuries easily withstand the increased metabolic demand and limited catabolism without nutritional supplementation. Those with severe injuries require replenishment of nutritional substrates to avoid excessive energy depletion and protein wasting. Nutritional formulas are provided by either the enteral or parenteral route. The beneficial effects of enteral nutrition include maintenance of gut mucosal barrier function and enhanced production of trophic gut hormones.

Although glutamine is the most abundant amino acid in the body, its concentration in plasma and tissues is depleted after injury. Studies have shown that glutamine-enriched nutrition can improve muscle protein synthesis and improve nitrogen balance. Arginine, a nonessential amino acid, has been shown to augment macrophage and natural killer cell activity. In critical illness, supplemental arginine improves nitrogen retention and wound healing. The majority of the experimental data on these immune-enhancing formulas is still too inconclusive to justify their use.

Summary

The acute trauma response consists of multiple biological components reacting to various signals from local wounded tissue and systemic alterations. In severe injury, exaggerated and unchecked release of mediators result in detrimental systemic effects and may lead to multiple organ failure. In addition to host endogenous modulation of these mediators, timely therapeutic interventions may modify local inflammation, neuroendocrine signals, and systemic alterations. Recovery from trauma ultimately depends upon the coordination of the neuroendocrine, immune, and metabolic systems toward restoring homeostasis and survival. Future research in this area may elucidate new therapeutic options for the critically injured trauma patient.

Properties of Adenylyl Cyclase

Adenylyl Cyclase in Stress

Glossary

Adenylyl cyclases Enzymes (EC 4.6.1.1) that generate the second messenger adenosine 3'5' monophosphate (cAMP) from ATP.

Heterotrimeric G-proteins

A group of proteins that consist of three subunits (α , β , γ) and couple cell surface receptors to their effector enzymes. On activation of cell surface receptors by their ligands, heterotrimeric G-proteins dissociate into the α subunit and the $\beta\gamma$ complex, both of which regulate the activity of effector enzymes such as adenylyl cyclase in the cell membrane.

Protein kinases

Enzymes that tag proteins with phosphoryl residues derived from ATP. The activity of protein kinases may be regulated by a variety of intracellular messengers, protein–protein interactions, or phosphorylation by other protein kinases.

Second messengers

Chemicals generated by extracellular stimuli arriving at the cell surface that transduce the extracellular signal toward the interior of the cell.

Properties of Adenylyl Cyclase

Signaling through cAMP is fundamentally important in the central nervous system. Genetic and pharmacological studies have revealed that alterations of both the synthetic (adenylyl cyclase, AC) and the catabolic (cyclic nucleotide phosphodiesterase, PDE) limbs of the cAMP cascade may cause a profound disruption of learning and memory. Further work has implicated cAMP signaling in the development of opiate dependence, alcoholism, the disorders of mood and affect, and neuronal death.

There are 10 genes encoding AC known in the human genome, and orthologs of all of these are found in mouse and rat. One of these genes encodes a soluble adenylyl cyclase that is a sensor for bicarbonate ions and is highly abundant in the choroid plexus but is otherwise absent from brain parenchyma. Nine of the genes encode enzymes that are integral membrane proteins. These ACs are differentially controlled by heterotrimeric G-proteins, Ca^{2+} , and protein phosphorylation (Figure 1). In turn, heterotrimeric G-proteins are regulated by seven transmembrane domain receptors on the cell surface. Several isoforms of adenylyl cyclase are expressed in the brain and show unique topographical distribution.

Figure 1 Schematic representation of mammalian adenylyl cyclases and their control. C1a and C2a, homologous catalytic domains (thick line); C1b and C2b, nonhomologous regulatory domains (thin lines); $\text{G}_{\beta\gamma}$, $\text{G}_{i\alpha}$, and $\text{G}_{s\alpha}$, G-proteins; M1 and M2, intramembrane domains; N, N-terminal cytoplasmic loop. Approximate sites of isotype-specific modulation reported for various cyclases to date are indicated in boxes along the polypeptide chain. The C1a and C2a domains must come into physical contact to form the catalytic core. This is facilitated by $\text{G}_{s\alpha}$, which binds to the C2a domain. Most adenylyl cyclases are inhibited by $\text{G}_{i\alpha}$, which binds to a site on the C1a domain.

Colocalization of ACs with distinct functional properties within the same cell has been demonstrated. This raises the possibility of the formation of cellular domains, for example, neuronal growth cones, where cAMP-dependent signaling has functional characteristics distinct from other parts of the cell such as the cell body. Further, the formation of subplasmalemmal microdomains with different types of ACs and PDEs also seems possible.

Some ACs such as AC types I and VIII are stimulated by intracellular Ca^{2+} and calmodulin. These enzymes are prominently expressed in the cerebral cortex and are important for learning and memory. Type I AC shows synergistic stimulation by Ca^{2+} /calmodulin and G_s -coupled receptors. Therefore, this enzyme may function as a co-incidence detector for the activation of ionotropic glutamate receptors and G_s -coupled receptors for a wide range of neuro-effectors. Another type of AC, isotype II, is synergistically stimulated by $\text{G}_{s\alpha}$ and $\text{G}_{\beta\gamma}$, or $\text{G}_{s\alpha}$ and protein kinase C-dependent phosphorylation. These properties suggest that the type II enzyme is a co-incidence detector for neurotransmitter receptors coupled to G_s and $\text{G}_{i/o}$, or G_s and G_q . These pairings are remarkable because they suggest that the direction as well as the magnitude of the effects of neurotransmitters on cAMP synthesis are dependent on the context of the stimulus applied. A third group of ACs is inhibited by Ca^{2+} ions. These enzymes are likely to participate in signaling circuits in which periodic surges of cAMP levels alternate with increases of intracellular Ca^{2+} (i.e., intracellular oscillations). Typically, in neuroendocrine cells, cAMP produces depolarization of the membrane potential and a rise in intracellular Ca^{2+} . The rise in intracellular Ca^{2+} triggers various effector mechanisms (e.g., secretion or gene expression) and will also provide negative feedback to the AC system to limit the rise of cAMP levels. Depending on the kinetics of cAMP synthesis and degradation, the cell may repolarize and return to the unstimulated state or enter a phase of oscillatory behavior.

Adenylyl Cyclase in Stress

Stressful stimuli increase the level of cAMP in the neocortex and the adenohypophysis. In the cerebral cortex, this is thought to be the consequence of the activation of AC through G_s -coupled receptors such as β_1 -adrenergic and corticotropin releasing hormone (CRH) type 1 and type 2 receptors. Mice overexpressing the CRH receptor present with an increased anxiety phenotype, indicating that cAMP could be an intracellular mediator of stressor activation. However, targeted deletion of the genes for AC I and VIII produced an anxious phenotype. Thus,

it is not warranted to generalize that cAMP is a mediator of stress and anxiety. In the anterior pituitary gland, cAMP is the major intracellular messenger activated by CRH. Here, the AC system operates as a co-incidence detector for activation by $G_{s\alpha}$, and protein kinase C-dependent phosphorylation.

Adrenal corticosteroid hormones interfere with the regulation of the cAMP pathway both in the short and the long term. Examples of long-term influence include control of the levels of AC in the neocortex and hippocampus. In these tissues, Ca^{2+} /calmodulin-stimulated AC activity is reduced by adrenalectomy and repeated stress. By contrast, the level of type II AC mRNA is increased by repeated stress in the hippocampus. An intriguing possibility is the induction of a protein called activator of G-protein signaling (AGS1, also known as Dex-ras1) by glucocorticoids. This intracellular protein activates G_i and thus reduces the biosynthesis of cAMP by ACs that are sensitive to $G_{i\alpha}$. Significantly, there are also ACs (isoforms II, IV, and VII) that are activated by $G_{\beta\gamma}$ subunits derived from G_i . Thus, by regulating the levels of AGS1, glucocorticoids could alter the characteristics of the cAMP response, essentially eliminating the action of receptors coupled to inhibitory G-proteins. With respect to short-term effects, in pituitary corticotrophs Ca^{2+} -mediated feedback inhibition of cAMP accumulation is essential for the early glucocorticoid feedback inhibition of adrenocorticotrophic hormone (ACTH) release stimulated by CRH. If cAMP levels rise above the range controlled by Ca^{2+} inhibition, glucocorticoid feedback is markedly diminished. This is the basis of the escape from glucocorticoid feedback induced by arginine vasopressin (AVP) at the pituitary level.

In peripheral tissues, cAMP is also a major intracellular mediator of the stress response in the adrenal cortex, liver, and fat tissue. The levels of cAMP degrading PDEs are increased by glucocorticoids in

adipose tissue; the effects on AC expression have not been studied so far.

Glossary

<i>Bereavement</i>	Loss through death.
<i>Bereavement process</i>	The umbrella term for bereavement reactions over time.
<i>Bereavement reactions</i>	Psychological, physiological, or behavioral responses to bereavement.
<i>Crisis</i>	A self-limited response to hazardous events and experienced as a painful state. It can last from a few hours to weeks.
<i>Diagnostic and Statistical Manual of Mental Disorders DSM-IV</i>	The latest and most up-to-date classification of mental disorders. It was published in 1994.
<i>Temperament and character inventory (TCI)</i>	A self-report questionnaire that allows diagnosis of personality disorders using a quantitative rating of seven factors, four dimensions of temperament (harm avoidance, novelty seeking, reward dependence, and persistence) and three dimensions of character (self-directedness, cooperativeness, and self-transcendence).

Definition

Adjustment disorder is characterized in DSM-IV by the development of emotional or behavioral symptoms in response to one or more identifiable psychosocial stressors. The symptoms are considered clinically significant because they either impair the individual's functioning or are subjectively perceived to cause distress in excess of what would be expected

from exposure to the stressor(s). These symptoms neither fulfill criteria for an Axis I diagnosis nor represent the exacerbation of a preexisting Axis I or Axis II disorder. They are not caused by normal bereavement. The symptoms occur within 3 months of the onset of a stressor and in response to it and do not last longer than 6 months after the end of the stressor or its consequences. The nature and severity of the stressors is not specified in DSM-IV. They include interpersonal, occupational, or medical problems. The stress may be single or multiple, such as loss of job associated with divorce and physical illness. The stress may happen once or it may be chronic, lasting more than 6 months (such as living in poverty), or recurrent (such as seasonal business difficulties). It can affect only one person or many (as in a flood or an earthquake). Whatever the nature of the stressor the person is overwhelmed by it. The individuals may experience anxiety, depression or behavioral symptoms (e.g., erratic actions) or various combinations. If the symptoms progress to meet criteria for another Axis I disorder (e.g., major depression), a diagnosis of adjustment disorder can no longer be used.

Historically a diagnosis similar to adjustment disorder first appeared in DSM-II. Transient situational disorder was understood in a developmental context and its subtypes were defined accordingly; for example, "adjustment reaction" of childhood, adolescence, or adulthood. It required an unusually severe stress. The term adjustment disorder first appeared in DSM-III. A link to severe and unusual stress was no longer required, and the subtypes were recategorized according to their symptomatic presentation. In DSM-II and DSM-III the duration of adjustment disorder was not specified. In DSM-III-R, the duration of the illness was restricted to 6 months after the cessation of the stressor, and the subtype adjustment disorder with physical complaints was added.

Epidemiology

The adjustment disorders are considered to be very common. One epidemiological study conducted in children and adolescents found a prevalence rate of 7.6%. Precise data are not available for adults because the structured interviews used in general population do not include adjustment disorder. Several studies of the prevalence of adjustment disorders were done in clinical samples including patients admitted in the hospital for medical or surgical problems. The reported rates were between 5 and 13%

in adults and up to 42% in children and adolescents. In a recent study of 1039 consecutive referrals to consultation–liaison psychiatry services, a diagnosis of adjustment disorder was made in 125 patients (12.0%). It was the sole diagnosis in 81 patients (7.8%) and in 44 (4.2%) it was diagnosed comorbidly with other Axis I and II diagnoses, most frequently with personality disorders and organic mental disorders. It had been considered as a rule-out diagnosis in a further 110 patients (10.6%).

Several studies found that this disorder is more common in women (sex ratio, 2:1).

Etiology

Adjustment disorder is caused by one or more stressors. There is a significant individual variation in response to stress so the severity of the stressors is not always predictive of the development of the illness.

Individual Factors

It is not clear why there is so much individual variation in the development of psychopathology in persons who experience similar stressors and also why when a reaction occurs the symptoms are so variable. Psychoanalytic researchers have highlighted the importance of development of adequate defense mechanisms as a child. Those who were able to develop mature defense mechanisms seem to be less vulnerable to and recover more quickly from the stressor. In this context, the roles of the mother and the rearing environment in a person's capability to respond adequately to stress are critical.

More recently, it has been shown that immature defense mechanisms correlate highly with poor character development as defined by the TCI (Temperament and Character Inventory). Poor character development is considered to be the common feature for the whole group of personality disorders as defined by DSM-IV. This implies that people who have a personality disorder are at a high risk for developing abnormal reaction to stress and then adjustment disorder. Conform to the definition both disorders can be diagnosed in the same time.

Several studies showed that children and adolescents are at a higher risk of developing an adjustment disorder than adults and that the illness is more frequent in females than in males.

Other Factors

The stressor severity is a complex function of multiple factors; for example, degree, quantity, duration, reversibility, environment, and timing. The severity of

the stressors is not always predictive of the occurrence and severity of adjustment disorder, but without a doubt, serious and/or chronic stressors are more likely to cause an adjustment reaction. It is not clear if all persons are likely to develop symptoms if stress levels are increased enough. The nosological and phenomenological distinction between crisis and stress is critical for the understanding of individual variability in response to stress.

Diagnosis

Diagnostic Clues

The chief complaint may be a nervous breakdown, inability to manage problems of life, or anxiety or depression associated with a specific stressor; the patient's history reveals normal functioning before the onset of the stressor; and the patient's mental status examination shows symptoms of anxiety, depression, or disturbed conduct.

Clinical Features

Several studies reported that between 50 and 87% of patients present with depressed mood. Other common symptoms encountered in more than 25% of the patients include insomnia, other vegetative symptoms (e.g., palpitations), behavioral problems, social withdrawal, and suicidal ideation or gesture.

The development of depressive symptoms alone is less characteristic of children and adolescents. Two recent studies found that among children and adolescents with adjustment disorder, the majority presented with mixed emotional or mixed emotional and behavioral syndromes. In one study, 77% of adolescents but only 25% of adults had behavioral symptoms (disturbance of conduct).

Studies of adjustment disorder that used structured diagnostic instruments have reported a high level of comorbidity. In a mixed group of children, adolescents, and adults, approximately 70% of patients with adjustment disorder had at least one additional Axis I diagnosis.

Several studies have reported a significant association of adjustment disorder with suicidal behavior in adolescents and young adults. A couple of studies done in patients hospitalized after a suicidal gesture showed that more than 50% of the patients met criteria for adjustment disorder with depressed mood. Three retrospective studies of suicide completers below age 30 found that between 9 and 19% of the cases met criteria for adjustment disorder. This data suggest the seriousness of the illness in a subset of persons.

Subtypes of Adjustment Disorder

The adjustment disorders are classified according to the predominant clinical symptoms. Six subtypes are identified and coded in DSM-IV. Three define discrete symptomatic presentations (depressed mood, anxious mood, disturbance of conduct) and two describe mixed clinical presentations (mixed disturbance of anxiety and depressed mood, mixed disturbance of emotions and conduct). The final subtype, adjustment disorder unspecified, is a residual category for presentations not accurately described by one of the other subtypes. One additional subtype, adjustment disorder with suicidal behavior, was proposed for inclusion in DSM-IV. It was ultimately rejected because of concerns that it would discourage a more systematic assessment of symptoms in patients presenting with suicidal behavior.

1. **Adjustment Disorder with Depressed Mood:** The predominant manifestations are depressed mood, tearfulness, and hopelessness. This type must be distinguished from major depressive disorder and uncomplicated bereavement.

2. **Adjustment Disorder with Anxiety.** Symptoms of anxiety – such as palpitations, jitteriness, and agitation – are present in adjustment disorder with anxiety, which must be differentiated from anxiety disorders. The patient is usually nervous, fearful, and worried.

3. **Adjustment Disorder with Mixed Anxiety and Depressed Mood:** Patients exhibit features of both anxiety and depression that do not meet the criteria for an already established anxiety disorder or depressive disorder.

4. **Adjustment Disorder with Disturbance of Conduct:** The predominant manifestation involves conduct in which the rights of others are violated or age-appropriate societal norms and rules are disregarded. Examples of behavior in this category are truancy, vandalism, reckless driving, and fighting. The category must be differentiated from conduct disorder and antisocial personality disorder.

5. **Adjustment Disorder with Mixed Disturbance of Emotions and Conduct:** The combination of disturbance of emotions (anxiety and/or depression) and conduct sometimes occurs.

6. **Adjustment Disorder Unspecified:** Adjustment disorder unspecified is a residual category for atypical maladaptive reactions to stress. Examples include inappropriate responses to the diagnosis of physical illness, such as massive denial and severe noncompliance with treatment and social withdrawal without significant depressed or anxious mood.

Adjustment disorders are also classified according to the clinical course. They are acute if the symptoms last less than 6 months and chronic if the symptoms last longer than 6 months.

Differential Diagnosis

Adjustment disorders must be differentiated from a normal reaction to stress or from other psychiatric disorders that occur following a stress.

1. In acute stress disorder and posttraumatic stress disorder, the stress needs to be severe and it is more clearly specified. The stressors are psychologically traumatizing events outside the range of normal human experience so they are expected to produce the syndromes in the average human being. Both acute stress disorder and posttraumatic stress disorder are characterized by a specific constellation of affective and autonomic symptoms, which is not encountered in adjustment disorders.

2. In normal bereavement, despite difficulties in social and occupational functioning, the person's impairment remains within the expectable bounds of a reaction to a loss of a loved one.

3. Other disorders include major depressive disorder, brief psychotic disorder, generalized anxiety disorder, somatization disorder, conduct disorder, drug abuse, academic problem, occupational problem, or identity problem.

4. If the criteria for any of the above disorders are met, that diagnosis should be used instead of adjustment disorder, even if a stressor was present.

Course and Prognosis

Course

Adjustment disorder begins shortly after a significant stressor. By definition, the symptoms have to commence within the first 3 months after the onset of the stressor. Usually they start in the first couple of weeks. In most cases when the stressor ceases the symptoms remit quickly.

Prognosis

By definition, adjustment disorder is not an enduring diagnosis. The symptoms either resolve or progress to a more serious illness. In most cases, the prognosis is favorable with appropriate treatment, and most patients return to their previous level of functioning within 3 months. It appears that children and adolescents have a poor prognosis. Several studies, which surveyed adolescents up to 10 years after a diagnosis of adjustment disorder, found that only 44 to 60% of

the original sample were well at follow-up. Some of the patients developed major mental disorders, such as schizophrenia, bipolar disorder, major depressive disorder, or substance-related disorders. It is not clear whether the poor outcome is due to adjustment disorder itself or to the frequent existence of comorbidity. At least one study that matched two groups for comorbidity (one with adjustment disorder and the other one without) found that adjustment disorder added no additional risk for poor outcome.

Treatment

Little is known about the proper treatment of adjustment disorder. There are few, if any, treatment studies in patients with adjustment disorder, and systematic clinical trials are necessary because adjustment disorder is one of the most common psychiatric diagnoses. The typical pharmacological intervention is always symptomatic. When given, medication is aimed to alleviate a specific symptom, but should always be in addition to psychosocial strategies.

Stressors

Whenever possible the etiologic stressors should be removed or ameliorated. Interventions designed to minimize the impact of the stressors on daily functioning should be considered.

Psychotherapy

This remains the treatment of choice for adjustment disorder. It can help the patient adapt to the stressor if it is not reversible or time limited. It can also serve a preventive role if the stressor does remit.

1. Crisis intervention is a brief type of therapy that may be useful to decrease stress and facilitate the development of external support. It is designed to resolve the situation quickly by supportive techniques, suggestions, reassurance, and environmental manipulation. The frequency and length of encounters with the therapist is tailored to the patients needs, and sometimes even short-term hospitalization might be warranted.

2. Individual psychotherapy offers the patient the opportunity to understand the personal meaning of the stressor and to develop coping skills.

3. Group psychotherapy can be remarkably useful for patients who experienced similar stresses; for example, a group of renal dialysis patients.

4. Family therapy can sometimes help in some patients, especially those with adjustment disorder with disturbance of conduct who may have difficulties with the school, authorities, or the law.

Pharmacotherapy

This may be useful in some patients when prescribed for brief periods. Depending of the subtype of adjustment disorder, an antianxiety agent or an antidepressant may help. Some patients with severe symptoms may also benefit from short course psychostimulant or antipsychotic medication. There are no studies regarding the use of specific medical agents in adjustment disorder. Few, if any, patients can be adequately treated by medication alone, and psychotherapy should be added to the treatment.

Conclusions

Adjustment disorders are an important and prevalent cause of personal discomfort, absenteeism, addiction, and suicide. This diagnosis should not be used to avoid stigmatization of a patient. Short psychotherapy is the treatment of choice, but pharmacotherapy is often used as an acute way to stabilize the patient and to prevent potentially disruptive behavior.

Introduction

Normal Adolescence

Common Stressors

Unusual Stressors

Glossary

<i>Adolescence</i>	A stage of life from puberty to adulthood usually thought of as occurring between the ages of 12 and 19 years. It is characterized by marked physical, psychological, and social change. The developmental task of adolescence is the change from dependence to independence.
<i>Identity</i>	A central aspect of the healthy personality, consisting of an inner awareness of continuity of self and an ability to identify with others, share in their goals, and participate in society.
<i>Puberty</i>	A normal growth process that begins in early adolescence, lasts 2–4 years, and leads to sexual and physical maturity.
<i>Resiliency</i>	The ability to overcome or adapt to stress by maintaining developmental progress and adequate social and academic functioning.

Introduction

Adolescence has been characterized as a challenging stage of life, defined by the psychological task of identity formation. Adolescents develop better coping skills as they mature both as a consequence of their cognitive and emotional development and because of the changes they experience. Teenagers generally respond successfully to many common stressors, such as puberty, school demands, family changes, and peer relations. Unusual stressors may lead to some difficulties, especially in those who are more vulnerable.

Traumatic stressors, although not universally harmful, often impinge on the emotional wellbeing of teenagers and may leave lasting scars. An adolescent's ability to cope with stressors depends on a

number of factors, including family support, cognitive development, previous experiences, and their own unique temperament.

Normal Adolescence

The discrete stage of adolescence has been recognized for only a short period of time. It seems to have come about in Western society as a consequence of the Industrial Revolution, when social changes necessitated the prolongation of childhood. Children, who had previously been able to enter the adult world at an early age, did not have the skills or abilities to perform adult work. Child labor laws were passed, and public schools were established. Families were also better able to financially provide for children for a longer period of time. The transition from childhood to adulthood lengthened, encompassing most of the second decade of life. Indeed, many teenagers nowadays maintain their dependency on their parents during college, thereby extending this transition even further. Puberty is often identified as the starting point of adolescence, although this can normally start as early as 9 or 10 years of age. The endpoint has been less well defined, as there are differences in the legal age of adulthood (18–21 years), and the criteria of independence, the completion of school, starting a new family, and getting a job are even more variable.

Adolescence is often thought of as a period of rebellion, marked by conflicts with parents as a child grows to be an adult. Anna Freud, G. Stanley Hall, and others characterized this stage of life as a time of storm and stress. Psychoanalysts believed that it was an indication of pathology if these stormy relations did not occur. Erik Erikson believed that the psychological task of this stage of life is the development of identity. Specifically, he thought that the adolescent would commit to a core set of values and assume a sex role and career plan. Failure to complete this task would result in identity diffusion, leading to further difficulties in adulthood. Adolescence was the period of an identity crisis, which led to considerable emotional turmoil.

However, Offer and associates have shown that the vast majority (~80%) of adolescents do not experience significant emotional distress. Instead, these teenagers manage the transition to adulthood smoothly, without experiencing a severe identity crisis. They have a positive self-image and are not afraid of the physical changes associated with puberty. They do not

report significant conflicts with their parents and have positive feelings toward their families. They are confident, optimistic about the future, and are willing to work hard in order to reach a goal.

However, a significant minority (~20%) of teenagers reports difficulties in these areas. They report that they feel emotionally empty and overwhelmed by life's problems. They feel much less able to control the world around them. These adolescents also report that they are much less able to talk with their parents about their problems. They appear to be more vulnerable to stressors and may exhibit more behavioral and emotional problems as a result. It seems that the stereotype of the moody, confused, and rebellious teenager is more applicable to this smaller group than to most adolescents.

Considerable cognitive development occurs during adolescence. Early adolescents become very self-conscious, which leads to a tendency to be more egocentric. They tend to believe that the thoughts and feelings that they have are unique. Furthermore, they do not seem to recognize that their peers are going through the same situation. In time, older teenagers become better able to empathize, to think abstractly, and to be introspective. They are able to consider possibilities and to imagine other realities. This leads them to become more philosophical, and to question the rules and realities of their lives in an attempt to gain a clearer understanding of the world. These cognitive abilities lead them to question their identity and to see themselves as individuals with some control over who and what they will be.

These changes become manifest in the adolescents' social environment. In particular, the family becomes less influential, while peer groups become more so. Adolescents begin to establish and exercise independence from parental controls. They learn to negotiate, although some conflicts arise. They spend more time with their friends than they did in childhood. They often imitate influential peers and adults. They try on different hats to see what they might look like, in order to establish an identity of their own. However, although they may dress like their friends or listen to music that their parents abhor, they often retain similar values and beliefs as their parents.

Adolescents tend to get better at coping with stress as they get older. They learn skills over time, utilizing their individual temperament and modeling parental coping strategies. Early in adolescence, teenagers tend to react defensively, denying problems, and thinking wishfully. They misinterpret situations, making mis-attributions to others, and overlooking information that would help them to see things more clearly. They also tend to either under- or overestimate both potential risks and their ability to handle them.

They may vent their frustration or anxiety in open emotional outbursts or they may withdraw and try to keep their feelings hidden. They seek solace and support from others, but do not readily ask for or listen to advice. As they develop, they become better able to appraise problems themselves. They try to change the stressful situation and to negotiate solutions. They learn that communication skills, the art of compromise, and assertiveness are more effective responses than are emotional outbursts or withdrawal. They learn how much of their feelings they need to reveal and become more adept at managing their emotions. They also become better at reading social cues and reacting appropriately. They think about ways to deal with problems and discuss potential solutions with others. Successful responses to stress lead to more success, although at times they may revert to previous, less effective strategies, usually in an impulsive fashion. Over time, most adolescents develop the skills necessary to cope with stress effectively, although some do not.

Common Stressors

Adolescents face a variety of challenges as a normal part of their lives. These include the physical and sexual changes associated with puberty; the demands of school; the desire to initiate and maintain friendships, both platonic and romantic; the need to start working and to make a career choice; and the gradual development of independence from the family. All of these changes can be stressful, but most teenagers report that they do not feel overwhelmed or unable to deal with them. Regardless of gender, socioeconomic status, or race, teenagers identify their most important concerns as career, school performance, and college plans. Many worry about violence, theft, and work. Some report concerns about peer conflicts and parental expectations. Teens are least worried about drugs and alcohol. Boys are more concerned about sexuality and extracurricular activities, while girls are more concerned about their appearance.

Puberty

Puberty, as the starting point for adolescence, is often thought of as very stressful. The physical changes are obvious, as is an increased sexual interest. Parents and teachers often attribute all behavioral changes to raging hormones, but the fact is that there are other social, and psychological factors that must be considered as well. Nevertheless, there is a biological effect of puberty on cognitive, social, and emotional development as well. In particular, the timing of puberty can be stressful and does seem to have an impact on academic and psychosocial functioning.

Boys appear to benefit academically and socially if they reach puberty early, although they often end up having a shorter stature than their later-developing peers. Early in adolescence, girls seem to have a better body image and are more popular if they develop early. However, as a group, they do not seem to do as well academically. Furthermore, by the time adolescence ends, later developing girls have a better body image than girls who reached puberty earlier do.

This may be related to the fact that girls with a later onset of puberty are more slender, which more closely fits with current cultural standards of attractiveness. More importantly, girls who reach puberty later have had a longer time to anticipate and adapt to these changes and as a result seem better able to cognitively process and cope with pubertal changes when they do occur. Finally, puberty may be most stressful when it is very early or very late, as this leads the adolescent to be markedly different from other peers. This information coincides with Offer's reports that most adolescents are comfortable with, and not distressed by, the changes of puberty, as most adolescents will enter puberty at about the same time as their peers and experience it as a normative process.

Peer Relationships

Peer relationships take on much more importance during adolescence. Teenagers expand their social relationships, looking to increase their connections with others. Girls in general seem to develop a capacity for intimacy sooner than boys do. Most teenagers believe they can make friends easily and that they can tell their friends intimate details about themselves. Early adolescents are very interested in being popular and want to fit in with a popular same-sex peer group. There is a degree of stress associated with this, especially if a young teenager wants to belong to a group, yet does not. Most are able to find a group, however, and do not find establishing friendships difficult. These peer groups are often very supportive and discourage deviant behavior.

In middle adolescence, boys and girls begin to mix. Romance and dating become extremely important. Once again, teenagers report some stress during this phase, as they grapple with the new social skills required to establish romantic relationships. However, most report that they believe they are interesting to members of the opposite sex and believe that they are capable of finding a romantic partner.

Dating usually begins between the ages of 12 and 16 years. Adolescents may face some peer pressure to date and may be dropped from a particular group if they do not do so. Similarly, they may feel pressure to engage in a similar level of sexual activity as their

peers. The pressure to conform to a perceived peer norm, which is in conflict with cultural, religious, family, or individual values, seems to be the most stressful aspect of romantic relationships. There are many similarities between adult and adolescent love relationships.

However, adolescent relationships are notably more transient, with strong feelings that do not usually lead to enduring intimacy or self-disclosure. Cognitive development as adolescence progresses helps teenagers to better cope with relationship changes. Gay adolescents are especially vulnerable to stress, due to feelings of isolation from peers and family and to difficulty integrating homosexuality into their identity.

Parents of teenagers frequently describe family life as stressful, due to the ongoing development of adolescent independence. This reflects a change in family roles, which parents may perceive as more difficult than adolescents do. Early adolescence is marked by considerable variation in roles, as the adolescent vacillates between asserting independence and maintaining dependency. There is some anxiety associated with becoming independent, felt by both parent and child. As they become older, most teenagers are confident about their ability to make decisions and try to demonstrate this to their parents. However, although they are in the process of individuating, they neither sever their emotional attachments to their parents nor become free of their parents' influences. Adolescents appear to be less distressed when parents utilize an authoritative parenting style which encourages and supports independence. Parents provide limits and controls with explanations, while allowing the adolescent to express their views. Nevertheless, tensions are still present as negotiations proceed and opposing needs are balanced.

Race and Culture

Racial and cultural issues pose interesting challenges, particularly for the adolescent. A child forms both gender and ethnic identities around the ages of 3–5 years. Children become familiar with cultural differences and history long before puberty begins. However, it is in adolescence that teenagers make a conscious commitment to be a member of their culture. They will generally embrace the values of their culture, which may not be the same as the dominant culture. This may lead to stress, especially if they have frequent interactions with peers of other cultures. They also can understand the abstract concepts of racism and inequality. They may be more likely to experience these as they leave their family and have more contact with peers and adults from other walks of life. Nonwhite adolescents are twice as

likely as their white peers to be funneled into the juvenile justice system rather than the mental health system when they have a problem with the law. They are also more likely to identify their main stressors as environmental ones (such as living in a dangerous neighborhood) rather than more personal ones. Most teenagers come to terms with their ethnic identity and with negative stereotypes and prejudices. They are able to accept themselves and their place within both society and their own ethnic culture. Those that do not do so have more difficulty with self-image and psychological adjustment. Adolescents who immigrate to a new country face additional stress, as they become more dependent on their families at a time when they are trying to develop independence. If they do push to be more independent, they may be more likely to join an inappropriate peer group.

Academics and School

School situations and academic demands are yet other common stressors that teenagers confront. The transition to middle school and the transition to high school are both major life events. Most teenagers report a combination of eagerness and apprehension as they move up to a bigger school with more challenging assignments, more complicated schedules, and more competent upper classmen. Middle schools represent a challenge as they are more impersonal and may require independence than early adolescents are capable of. Most middle-school students have not mastered the social skills needed for this setting, although they may learn them quickly if provided with opportunities to succeed in small groups.

High schools offer more extracurricular activities, which provide opportunities to join in new peer groups, but the many choices may be overwhelming and confusing, and some adolescents may end up feeling excluded. Grades become more meaningful, especially for those planning on college. Parental expectations, Scholastic Amplitude Test (SAT) scores, and college applications create tension, as does the search for a job after graduation.

Work

Most teenagers express a desire to work and feel satisfaction in a job well done. Earning money helps older adolescents become more independent and enables them to practice some of the skills they will need as adults. However, trying to balance a part-time job with school demands, sports, and social activities is often difficult. Adolescents who work are less invested in school, spending less time on homework and missing classes more often than peers who do not

work. They usually work in low-paying jobs and have little authority or opportunity to advance. Those who work the most hours tend to have the lowest grades. However, part-time work has also been associated with better self-esteem and a sense of responsibility in adolescents. Teenagers cope with the stress of work best if they can balance the time they work with their other priorities. Working raises other issues, as adolescents may be overwhelmed with the choices they have.

Establishing a life goal is a daunting task for adolescents. Many are reluctant to commit to a specific career path, as this means eliminating other possibilities. This lack of commitment may be interpreted as a lack of motivation by parents, leading to conflicts. Adolescents also have many misconceptions and cognitive distortions about themselves and the careers they are considering. Accurate information and a frank discussion of their strengths and weaknesses are important. The support of a mentoring adult is often very helpful, as is providing the perspective that any choice is not etched in stone. This issue is also one that tends to extend adolescence most often, as it is commonly the last one resolved.

Unusual Stressors

Some teenagers face more unusual challenges. These can include family problems, such as mental or physical illness; drug or alcohol abuse; parental separation or divorce; social problems, such as poverty and violence; and individual problems, such as pregnancy, serious illness, and school failure. In some instances, teens may experience traumas such as abuse or the death of a loved one. Adolescents with adequate cognitive abilities, emotional development, and supportive families seem better able to cope with these problems successfully. Teenagers who have experienced multiple stressors, have a previous history of psychopathology, or have little parental support are much more vulnerable.

Parent with Medical/Psychiatric Illness

Adolescents who are raised in homes where a parent has a serious medical or psychiatric illness have the ability to understand the illness better than younger children and may have more questions as a result. They are also more likely to exhibit anger and acting out behaviors. This may occur because of the conflict involved between the family's needs for help from the adolescent and the adolescent's needs to become more independent. Younger children may be more likely to avoid discussion of the parent's illness and to experience intrusive thoughts and feelings, while adolescents are more likely to exhibit symptoms of anxiety and depression. This is particularly true of teenage

girls whose mothers have cancer. Parental coping skills play a part in how adolescents respond to parental illness. Parents who are less anxious and depressed have a positive effect on their children. There are some important differences to be considered when a family member has a severe mental illness as opposed to a physical illness. Parents with mental illness are much less likely to be in treatment, which means that professional education and advice are much less forthcoming. There is considerable stigma associated with mental illnesses (although some physical illnesses carry a stigma, such as HIV infection). Adolescents may therefore be much less likely to seek peer or adult support as a result. Teenagers are at a higher risk for depression and other mood disorders when their parents have a chronic mental illness, but studies have not been able to separate genetic influences from psychosocial effects on children and adolescents. Finally, parental conflicts, divorce, and inconsistent parenting practices often are present in families where a parent has a severe mental illness. These multiple risk factors compound the stress on an adolescent, more so than in families where a parent has a severe physical illness. Adolescents who cope best when parents have a serious medical or psychiatric illness share several characteristics. They tend to be actively involved in school, church, work, and other outside activities. They have a close relationship with a supportive adult. They also understand that they are not responsible for their parents' illness. Their families are more cohesive, flexible, and are able to maintain family rituals. Finally, their families effectively communicate information and feelings about the parental illness and are able to make plans for the future.

Parental Alcohol Abuse

The effects of parental alcohol abuse have also been studied, although more attention has been paid to younger children in alcoholic families. Adolescents raised in alcoholic families have been found to have a higher risk of conduct disorder, substance abuse, sexual acting-out, physical and sexual abuse, and academic problems. They also have more difficulties in their peer relationships and are more likely to have romantic relationships with adolescents with substance abuse problems themselves. Some adolescents may take on a more adult role within the family in an attempt to maintain family functioning, while others may disengage. Boys seem to have a higher risk of problems than girls do. Teenagers who cope effectively with parental alcoholism tend to have healthy and supportive relationships with adults outside of the family. Families that are able to maintain family rituals (e.g., such as holiday celebrations,

family dinners, and church attendance) have teenagers that are more resilient in the face of parental substance abuse.

Adolescents with an easy temperament, at least average intelligence, and an internal locus of control are also more resilient. Not all teenagers from alcoholic homes require treatment, although parents with alcoholism should be referred for treatment. However, it is not clear what effect, if any, parental recovery has on adolescents who are already exhibiting problems. Alateen, a self-help program for adolescents from alcoholic families in the USA and Canada, has been effective in providing information and improving mood and self-esteem for teenagers. Group, individual, and family therapy have been helpful. All interventions should provide education regarding the adolescent's increased risk of substance abuse in an attempt at prevention.

Parental Marital Conflict and Divorce

Parental conflict and divorce is a fairly common, but nonetheless major, stressor in today's culture. Most research on separation and divorce has focused on younger children. Studies with adolescents suggest that they too may have difficulty adjusting to this stressor. In addition, children who experience divorce may not manifest problems until adolescence. It is important to remember that most children and adolescents do adapt to divorce and are able to function effectively as adults. Younger adolescents whose parents divorce are more likely to be noncompliant and aggressive and to have problems with substance abuse than are adolescents in nondivorced families. Gender differences have been reported. Adolescent girls from divorced families have had more problems with self-esteem and promiscuity, while adolescent boys have a higher incidence of substance abuse. Both boys and girls have lower academic achievement, but teenage boys are also likely to drop out of school if their parents have divorced and they are living with their mother. Girls are at a greater risk of dropping out if they live with their remarried mother and stepfather. These findings appear to hold even when factors such as race and socioeconomic status are controlled for. Conflict between divorced mothers and their adolescent daughters is common, possibly connected to the teenage girls' tendency to increased sexual acting out. Adolescent boys have a higher risk of disengaging from their family and to engage in delinquent behavior with peers. This may be related to the absence and lack of influence of the noncustodial father, which is all too common in divorce. Many factors mediate adolescents' responses to divorce. An authoritative custodial parent seems to be the most important factor, as the parent is able to provide

the understanding and support needed while maintaining an authority position in the family. Generally, teenagers are better able to cognitively process and understand the reasons for parental divorce than younger children are. However, those who have limited insight, poor problem solving skills, and a history of temperamental difficulty are more vulnerable to experiencing problems with the divorce. The degree of conflict between parents and the amount of contact with each parent are also important. Depression and delinquency have been connected to prolonged parental conflict.

Poverty and Violence

Sociocultural stressors such as poverty and violence have long been recognized as stressful for children and adolescents. However, it is very difficult to disentangle the specific effects these stressors have from each other as well as from other associated risk factors, such as parenting styles and other environmental stressors. Approximately 20% of American children live in poverty – the highest rate for any Western industrialized country. Black children are twice as likely to experience poverty as white children are. Length of time spent in poverty varies, although around 90% of poor children spend less than 5 years in poverty. Contrary to popular belief, poverty is more common in rural rather than urban areas.

Adolescents who experience poverty have a higher rate of delinquency, depression, and poor self-image. They may also incorporate the idea of poverty into their identity rather than to see it as a temporary external condition. Again, parental responses and styles have a marked effect on adolescent coping strategies. Families living in poverty are more likely to utilize inconsistent, punitive, and authoritarian parenting styles, which leads to increased stress and conflict. In contrast, poor but supportive parents, who have a positive outlook on the future, have less distressed teenagers. Teenagers are also able to recognize when they live in less desirable neighborhoods and are well aware of the risks of violence. Living with this chronic stress is difficult and can have a marked effect on their outlook on the future. They may be more fatalistic and experience more posttraumatic stress disorder (PTSD) symptoms as a result of their exposure to violence. Anecdotes abound, both describing those who have problems and those who have been resilient. However, at this time there are no systematic studies that have assessed these issues.

Pregnancy

Some teenagers face significant individual stressors, such as pregnancy, serious illness, or school failure.

These teenagers already tend to be at a higher risk for other stressors, as outlined above. However, considerable study has been given to these issues. Teenage girls who get pregnant are less prepared than their adult counterparts to raise children. They know less about infants and are more distressed by the pregnancy. Around 40% choose abortion, while 45% choose to keep their child. The other 15% either miscarry or choose adoption. Teenage mothers are less responsive to the needs of their babies than are adults. However, longitudinal studies have shown that a majority of teenage mothers complete high school and hold regular employment thereafter. Most support themselves and their children, although they are on welfare at times. They do not end up having more children than peers who have children later. Most importantly, the majority seems to cope effectively over the long run.

In contrast, teenage girls who ultimately choose abortion report considerable psychological distress during the time of pregnancy. This seems to fade somewhat after the abortion. However, studies of women who have undergone abortion indicate that most negative reactions and distress occur in those who are young, unmarried, previously nulliparous, and who delay the procedure until the second trimester. Adolescents are much more likely to fit into this profile and so appear to be at a higher risk for psychological sequelae as a result of the abortion. The debate about the psychological effects of abortion is unresolved, as this particular group remains difficult to study due to the many other stressors that they face.

Serious Illness

It is estimated that 5–10% of teenagers face a serious illness during adolescence. Adolescents who suffer from serious illnesses struggle with a variety of issues. Early adolescents tend to try to deny the existence of their illness, using avoidant coping strategies. These problems are more likely to occur in families where there is little cohesiveness. This often leads to treatment noncompliance and more problems with the illness itself. Conversely, chronic or serious illnesses may impair normal adolescent development.

This seems to be due to the fact that the illness and treatment requirements make the adolescent more dependent on his parents. They in turn may be more unwilling to let the teenager be more independent. Adolescents may also incorporate their illness into their identity. In some situations, such as diabetes, these may be unavoidable due to the nature of the illness. For those who have cancer, however, this may be more problematic. Adolescents with a history of cancer are not more likely to be depressed, but they

are more likely to have somatic complaints and preoccupations and to be distrusting of their bodies. They also tend to have greater difficulties in romantic relationships. Misattributions and misunderstandings about their illness and its prognosis should be addressed when present. Parents and adolescents often need much more education and support than they receive. Efforts should be made to help adolescents understand both their illness and treatment, and information should be made readily available to them. This should occur in a stepwise fashion, allowing teenagers some time to adjust to changes and react to them emotionally and intellectually.

Dropping Out of School

Approximately 10–15% of adolescents drop out of school. Often, they have parents or siblings who have done the same. Parental attitudes about education have a great impact on academic performance, even in adolescence. Adolescents whose home lives are already distressed or whose fathers are absent are much more likely to drop out. Those who have already failed a class or who have been held back a grade are at greater risk as well. Many are working, and many have children. Teenagers find dropping out is very stressful and would recommend against it. Job opportunities are limited and they are often unable to function independently. Successful prevention requires strong cooperation between parents and schools, providing the support and guidance necessary to vulnerable teenagers.

Peer Victimization

Several forms of adolescent victimization have been recognized, including bullying, sexual harassment, and interpersonal violence and emotional abuse in dating relationships. Research is limited, but most adolescents have had some limited experiences of victimization. There may be significant differences based on gender, socioeconomic status, and racial and ethnic groups. Those teenagers who complain of significant levels of psychological distress tend to have been targeted on multiple occasions, and in several forms of victimization. They also feel less of a sense of school belonging. In addition, adolescents who have experienced bullying are more likely to have self-blaming attributions than those who have not. Clinicians and school personnel should be carefully assessing for the occurrence of victimization in multiple areas if a teenager reports experiencing any one form of victimization.

Trauma Trauma often leads to emotional and behavioral changes. Most studies on trauma have

looked at younger children, children and adolescents together, or at adolescents who were traumatized as children. However, adolescents can be abused physically, sexually, emotionally, or in combination. Due in part to their increasing independence and to their cognitive and emotional development, adolescents are less likely than are children to be abused by family members. However, they are more likely to be the victims of rape, assault, or robbery than younger children or adults. There are some gender differences in adolescents, as girls are more likely to experience sexual trauma, while boys are more likely to witness the injury or death of another. Catastrophic life events also may occur, including the death of a parent, sibling, or peer due to illness, accident, violence, disaster, or terrorism. Although age-based differences in stress reaction have received research attention, findings have been inconsistent, due in large part to the lack of normative and pretrauma psychological functioning data.

Teenagers who have been abused may come to attention for incidents that have just recently occurred and been disclosed or may have occurred many years earlier. The length of time since the occurrence of abuse or trauma does not mitigate the severity of symptoms or the need for treatment. It is also not clear if abuse or trauma at an earlier or later age leads to more problems. Adolescents are less likely to be abused than are young children. However, many adolescent victims of abuse have been abused as children. Therefore, teenagers who present with physical or sexual abuse may have a lengthy history of abuse and may have more difficulty as a result.

Multiple neurotransmitter systems are involved in the response to traumatic stress, and chronic stress has been associated with long-term changes in neuronal function in structure. A comprehensive study by De Bellis et al. demonstrated alterations in biological stress systems and adverse influences on brain development in maltreated children and adolescents with PTSD. Increased levels of catecholaminergic neurotransmitters and steroid hormones during traumatic experiences could negatively affect brain development. Causal relationships have not yet been established, however, and it is unclear how traumatic stress specifically affects the still developing adolescent brain.

Abuse Teenagers who have been sexually abused are less likely to show unusual sexual behaviors or preoccupations than are young children. Abused teens also are more likely than children to disclose purposefully, usually out of anger toward the perpetrator. Adolescents are also more likely to have their reports substantiated. However, because they are older, victimized adolescents may be blamed, just as

women who are victims of domestic violence are often blamed for not seeking help or leaving an abusive situation. In addition, adolescents who are physically abused may be seen as provoking a parent, thereby earning physical discipline. This is particularly true in teenagers who have a history of physical aggression, threats, delinquent behavior, noncompliance, and/or defiance. The juvenile justice system is more likely to be involved in these situations and may be less cognizant of the possibility of abuse than either mental health or child protective services.

When evaluating adolescents who have been abused, it is important to be sensitive and to allow them some control over what, when, and how much they disclose. Teenagers will often want to avoid talking about the issue and to minimize the effects it has had on them. Recognition and support for their attempts to cope with the abuse should be provided, in keeping with their psychological development, especially their need to be independent and successful. In addition, it may be helpful to separate the problem from their identity as a person. Hecht et al. suggest a statement such as, "I've talked with a lot of people your age who have been through sexual abuse. We talk about the effects it has had on them. Everyone's different, but I want to find out if some of the things that have bothered other young people have bothered you. I'd also like to find out what sorts of things you have done that seem to help the most." It is also important to understand the adolescent's attributions about the abuse. As adolescents are more independent and society holds them more responsible for their actions, they may be more likely to blame themselves.

Furthermore, teens may want to maintain the idea that they have control over what happens to them, in keeping with their developmental stage. At the same time, adolescents will often fear disclosure to their peers, perhaps believing that they will be stigmatized or that their peers will hold them responsible.

Nevertheless, having the support and understanding of a peer is often very helpful. In assessing an adolescent who has been abused, it is important to obtain a complete history as well as to address possible PTSD symptoms. In addition, any problems with aggression, impulsivity, social skills, attention span, academic performance, depression, anxiety, substance abuse, and delinquency should be explored. Abused adolescents are also at a higher risk for eating disorders, sleep problems, and self-injurious behavior.

Treatment interventions should be individualized, but may include sexual education, information about PTSD symptoms and abuse, and, perhaps most importantly, an attempt to work out with the adolescent an explanation as to why the abuse happened. Group

and individual therapies have both been utilized with success. Treatment interventions should address both the needs of parents and the adolescent. Social skills, problem-solving, and cognitive treatments have been effective with adolescents, but family interventions in particular seem to help maintain progress over the long term. Court-mandated treatment helps to keep abusive parents in treatment.

Death Adolescents rarely experience the death of a parent, sibling, or of a close friend. Furthermore, studies of children who have lost a parent usually group younger children with adolescents. As a result, unique characteristics of adolescent bereavement are difficult to identify. Adolescents are able to conceptualize death abstractly. This allows them to consider religious and philosophical issues and may lead to more uncertainty than in younger children. Adolescents who have never experienced a death have a difficult time adjusting to this change. Adolescents who have experienced the death of a parent are at a higher risk for delinquency, anxiety and depressive symptoms, somatic complaints, and PTSD symptoms. Adolescents who have experienced a disaster are more likely to experience PTSD symptoms if they lost a loved one (parent, friend, or classmate) in the event. However, displacement from home, community, and school also contributes to these problems.

Teenage boys who lose a father are at a higher risk for behavioral and emotional problems as are early adolescents. Sudden deaths are clearly more difficult to cope with than deaths that occur after a protracted illness, as adolescents have a chance to prepare emotionally and intellectually for the event. However, a strong and supportive surviving parent can offer some protection. Once again, teens that can confide in another adult (such as a relative, teacher, or neighbor) seem to cope better, as they are able to talk about their dead parent openly. It is important to remember that subsequent events, such as graduation, making a sports team, dating, or getting a job, may reopen grief feelings and should be considered as additional stressors. Nevertheless, the majority of adolescents appear to cope effectively with the death of a parent. The death of a peer is also a rare event. Studies in this area have been limited and have primarily focused on peers who commit suicide. In these instances, adolescents have exhibited depressive symptoms, but have not had an increase in suicide attempts.

Risk Factors for Suicide in Adolescents
Neuroscientific Findings in Adolescent Suicide
Treatments and Possible Effects of Antidepressants

Glossary

Serotonin (or 5-hydroxytryptamine; 5-HT) An indole amine that is a key chemical neurotransmitter in the nervous system. Disordered serotonin transmission is implicated in depression, suicide, schizophrenia, anxiety and other mental disorders.

Serotonin receptors Receptors are docking sites for bioactive molecules such as serotonin. There are more than 15 serotonin receptor subtypes all located in the cell membrane. With the exception of the 5-HT₃ receptor, a ligand gated ion channel, all other 5-HT receptors are G protein coupled seven transmembrane (or *heptahelical*) receptors that activate an intracellular second messenger cascade. The different

subtypes subserve different functions and are targets for different drugs. Thus, for example, the 5-HT_{2A} receptor is the docking target for the hallucinogen, Lysergic acid diethylamide (LSD). The serotonin transporter (SERT) is a 12-transmembrane protein that mediates serotonin uptake (back into the neuron) and thus reduces extracellular serotonin levels in the brain and especially at synapses. SERT is a major target for therapeutic intervention, and the selective serotonin reuptake inhibitors (SSRIs) are the most frequently prescribed antidepressants worldwide. Increased synaptic serotonin concentrations generated by SSRIs are thought to alleviate depression.

Serotonin transporter

Adolescent suicide is a serious public health problem. According to the most recent statistics, suicide is the third leading cause of death among 10- to 24-year-olds in the United States, accounting for 11.7% of all deaths in this age group. Nonfatal suicide attempts are also a significant concern in their own right. In 2002, approximately 124 409 visits to U.S. emergency departments were made after attempted suicide or

other self-harm incidents among people ages 10–24 years old. According to data obtained as part of the Youth Risk Behavior Survey, a national survey administered to high school-age youth in 2003, approximately 17% reported having seriously considered attempting suicide, 16.5% reported having made a plan for suicide, 8.5% reported having attempted suicide, and 2.9% reported having made a suicide attempt that required treatment by medical professionals. Suicide attempts can lead to injury, place youth at increased risk for death by suicide and future suicide attempts, place burden on the health-care system, and are associated with a range of adverse outcomes including substance abuse, high-risk sexual acts, school drop-out, poor academic performance, and delinquency.

Risk Factors for Suicide in Adolescents

Prior suicide attempts are the biggest risk factor for a subsequent suicide attempt or completed suicide. Psychopathology is a risk factor for suicide attempts. Approximately 90% of suicide victims have a psychiatric illness at the time of their death. Significant increases in the risk of suicidal behavior are associated not only with depression but also with psychosis, substance abuse, disorders that involve impaired impulse control, and a variety of other psychiatric disorders.

Epidemiological studies of adolescent suicide have demonstrated an increased risk of suicidal behavior with age and significant gender effects that depend entirely on the distinction between completed suicide and suicide attempts. Suicide is relatively uncommon before age 12, and incidence rates rise in the late teens and early twenties. Suicidal ideation and suicide attempts are more common among females than males. In contrast, completed suicide is three to five times more common among males than females. The higher rate of completed suicide in males has been attributed to a variety of factors, including the use of more lethal methods (such as firearms) and higher rates of aggression and substance abuse. The most common way that females attempt suicide is to overdose. In some countries where more lethal drugs are accessible or where emergency medical care is less effective, the rate of completed suicide in females exceeds that of males. Race has been demonstrated as a risk factor for completed suicide. Completed suicide is more common in Whites than African Americans in the United States. The highest rates are among Native Americans and the lowest are among Asian/Pacific Islanders. Similar rates have been described for suicide attempts and recent data suggest that some

groups, such as Hispanic females, may be exhibiting more frequent suicide attempts over recent years.

When evaluating an adolescent's risk for suicide, late adolescent age, male gender, and Native American race suggest a higher risk. The presence of significant psychiatric illness, substance abuse/intoxication, and particularly past suicide attempts also increase an individual's risk. In addition, the presence of significant family conflict, dysfunction with peers, or hopelessness increases the risk of suicide.

Neuroscientific Findings in Adolescent Suicide

Several psychiatric disorders now have a significant and growing body of evidence supporting genetic susceptibility to the disorder and underlying neurological or neurochemical abnormalities. Distinct findings in suicidal patients independent of a specific psychiatric diagnosis have been described. For example, structural brain abnormalities identified as white matter hyperintensities on magnetic resonance imaging (MRI) have been associated with suicide attempts in depressed adolescents. Several studies have described abnormalities present in the serotonin neurotransmitter systems in both suicide attempters and completers. Specifically, decreased serotonin transporter binding and increased serotonin receptor density have been reported in a number of studies and may represent a possible mechanism for a heritable risk for suicidal behavior.

Treatments and Possible Effects of Antidepressants

The U.S. Food and Drug Administration has issued warnings of a possible increase in suicidal behavior in individuals being treated with antidepressant medications. These warnings originated as a result of analyses of published and unpublished data on the use of antidepressants in adolescents that indicated approximately a 2% increase in the rate of suicidal behaviors (but not completed suicides) in treated versus placebo groups. These warnings contrast with other findings, including a clear decrease in the overall suicide rate beginning with the widespread use of antidepressants, the absence of antidepressant medication in the majority of the postmortem analyses of completed suicides, and the demonstrated efficacy of antidepressants in adolescent depression. Current practice guidelines include enhanced monitoring for suicidal behaviors during the initial weeks of antidepressant therapy.

Research into psychotherapeutic treatments targeting suicidal behavior in adolescents has demonstrated

benefits for family- and community-based interventions and for cognitive-behavioral interventions that target preventing repeat suicidal behavior by improving adolescents' problem-solving skills, decreasing hopelessness and negative cognitions, and improving their ability to regulate negative emotions. Common factors in treatment approaches to suicidal adolescents involve identifying and treating risk factors such as underlying depression, substance abuse, and family stressors. Acutely suicidal patients are treated first for any injuries they have sustained and next with inpatient hospitalization or some equivalent level of supervision to assure their safety. When patients are no longer in danger, medication and psychotherapy can be provided on an outpatient basis, with the goal of preventing a future suicide attempt.

Structure of the Adrenal Cortex
Hormones of the Adrenal Cortex
Control of Adrenocortical Secretion
Actions of Corticosteroids

Glossary

Aldosterone The principal mineralocorticoid secreted by the adrenal cortex.

Angiotensin II An octapeptide that provides the major hormonal support of the growth and function of the zona glomerulosa of the adrenal cortex and of aldosterone secretion.

Cortex The outer, steroid-forming part of the adrenal gland.

Corticosteroids The collective name for the steroid hormones (glucocorticoid and mineralocorticoid) that are secreted by the adrenal cortex.

Corticosteroid-binding globulin (CBG) The carrier protein to which cortisol binds in the circulation.

Corticotropin (corticotropin, adrenocorticotrophic hormone, ACTH) The pituitary hormone that largely controls growth and activity of the adrenal cortex, particularly the zona fasciculata and cortisol secretion.

Cortisol The principal glucocorticoid secreted by the adrenal cortex.

Cytochrome-P450 A family of enzymes associated with the synthesis of steroid hormones that utilize molecular oxygen to form hydroxyl groups on the steroid molecule.

<i>Dehydroepiandrosterone (DHEA, or DHA)</i>	By amount the major androgen-like hormone secreted by the adrenal cortex.
<i>Glucocorticoids</i>	Steroid hormones (especially cortisol) from the zona fasciculata of the adrenal cortex that affect carbohydrate metabolism.
<i>Medulla</i>	The inner, catecholamine (adrenaline)-secreting core of the adrenal gland.
<i>Mineralocorticoids</i>	Steroid hormones (especially aldosterone) from the zona glomerulosa of the adrenal cortex that affect mineral (especially sodium/potassium) homeostasis.
<i>Renin-angiotensin system (RAS)</i>	The blood-borne complement of enzymes and substrates that gives rise to angiotensin II.
<i>Zona fasciculata</i>	The middle part of the adrenal cortex, secreting glucocorticoids, especially cortisol.
<i>Zona glomerulosa</i>	The outer, mineralocorticoid (especially aldosterone)-secreting part of the adrenal cortex.
<i>Zona reticularis</i>	The inner part of the adrenal cortex, secreting both glucocorticoids and androgens, but also containing apoptotic (dying) cells.

Structure of the Adrenal Cortex

The adrenals are paired glands lying close to the anterior part of the kidney. Their combined wet weight is about 0.01–0.02% of the total body weight, and thus they weigh about 8 g in the adult human in both males and females.

Morphology

The gland has two main parts, the medulla at the center and the cortex surrounding it. These two parts have different developmental origins; the medulla forms part of the sympathetic nervous system, whereas the cortex, like the gonads, has a distinct embryological origin in the germinal ridge. The medulla and cortex also have different functions, though both are associated with the response to stress. Their functional differences lie both in the nature of the hormones they produce – catecholamines such as adrenaline and noradrenaline from the medulla and steroids from the cortex – and the ways in which these secretions are controlled – by neural stimulation in the case of the medulla, but by other hormones circulating in the blood in the case of the cortex.

Histologically, the cells of the adrenal cortex are arranged as three major layers, or zones, organized as concentric shells. The cells of the different zones are

generally distinguished by their shape and size and by their ultrastructure as well as by their arrangement and position within the gland. The three zones are called the *zona glomerulosa*, the *zona fasciculata*, and the *zona reticularis*. Broadly, the zona glomerulosa lies just below the connective tissue capsule and consists of whorl-like arrangements of cells. Cells of the zona fasciculata are arranged as a series of cords running centripetally, which extend to the less clearly organized network of cells of the zona reticularis (see [Figures 1 and 2](#)).

Other zones are recognized in different species, although these are usually smaller and may be transient. In humans, the most prominent of these is the fetal

Figure 1 General structure of the mammalian adrenal cortex showing the positions of the zona glomerulosa (zg), zona fasciculata (zf), and zona reticularis (zr) and their relationship to the capsule (c), nerve cells (n), arteriolar supply (a), medullary arteries (ma), sinuses (s), medulla (m), and isolated islets (i) of chromaffin (medullary) cells lying in the inner cortex. Neuroendocr.* 6, 235–246, Blackwell, Oxford.

Figure 2 General structure of the human adrenal gland. Arrangement of adrenal cortex in the region of the cortical cuff. Notice the folding results in a doubling of the cortical thickness and the juxtaposition here of the inner zona glomerulosa and the central vein in cortical cuff region. M = medulla; ZG = zona glomerulosa; ZF = zona fasciculata; ZR = zona reticularis; V = central vein. Drawing by B. Landon. Figure reproduced with permission from G. P. Vinson and J. P. Hinson, *The Adrenal Gland* (V. H. T. James ed.), pp. 71–85, Raven Press. ©1992 Lippincott Williams & Wilkins.

cortex (see below). The cells of the cortex are renewed from a region just below the glomerulosa; this may be the role of the cells of the zona intermedia, which has been described as a small band of cells in some species. The cells migrate centripetally over a period of time, and as they do so, they acquire the functional and morphological characteristics of the cells of the zones that they pass through.

In humans, the zona glomerulosa seldom occupies more than 5% of the total cortical volume and its cells are gathered into more or less isolated islets. The cells are relatively small and round, with a high nuclear-to-cytoplasmic ratio. Ultrastructurally, the mitochondria of zona glomerulosa cells are characterized by their lamelliform or shelflike cristae. The smooth endoplasmic reticulum is sparse; ribosomes and polysomes are visible throughout the cytoplasm.

The zona fasciculata cells are larger, with abundant cytoplasm, and the mitochondria contain tubulovesicular cristae, although these may vary between the outer and inner parts of the zone. In conventional stains, these cells are lighter in appearance than zona reticularis cells and hence have been termed *clear cells* as opposed to the *compact cells* of the zona reticularis, which stain more deeply.

The zona reticularis occupies one-third of the cortex, and its cells are intermediate in size between those of the zona glomerulosa and zona fasciculata. The mitochondria of zona reticularis cells are elongated with tubulovesicular cristae; microbodies (lipofuchsin granules) and lipid droplets also occur.

In humans the adrenal is prominent in fetal life, when it reaches a maximum of about 0.3% of body

weight. This declines slightly in the third trimester and precipitously in the neonate. The large size of the gland is attributable to the presence of an additional zone – the fetal zone – which lies between the definitive cortex and the medulla. The cells of the fetal zone are larger than those of other zones and stain only palely in conventional histology. In the fetus, the cells of the definitive cortex contain lamelliform cristae (like the zona glomerulosa of the adult gland), whereas the mitochondria of the fetal zone cells are tubulovesicular. Studies on the origin and ultimate fate of the cells of the fetal zone are inconclusive. Some have held that the fetal zone cells arise from a second discrete proliferation, although this has been contested, and they may arise, like the reticularis, from the outer zones. Similarly, there are two explanations for its disappearance after birth; one that the zone involutes, the other that it is transformed into elements of the definitive cortex.

Circulation and Innervation

The intraglandular circulatory system deserves some attention, particularly because of its responses during stimulation. The adrenal is one of the most highly vascularized organs within the body, and detailed studies have shown that virtually every cell borders the thin and attenuated endothelial cells which line the vascular space (see [Figure 1](#)). The general pattern in mammals is as follows: a variable number of arteries supply the gland which divide in the capsular or subcapsular region to form an arteriolar plexus. Two types of vessels arise from this plexus: first, there

are the thinly walled capillaries, frequently called sinuses, which run centripetally through the cortex. These are the most abundant of the cortical vessels and may be assumed to supply all of the cortical cells. Second, there are the much more sparsely distributed medullary arteries, with thicker walls, which run through the cortex to supply the medulla directly. It is likely that blood from the cortical sinuses and the medullary arteries mixes in the medulla, and, on the basis of the relative abundance of the vessels, it is reasonable to assume that the medulla receives most of its supply from the sinuses. Accordingly the cortex exerts an endocrine control over the medulla, and, in particular, glucocorticoids (see below) are required for the development in the medulla of a key enzyme required for the synthesis of adrenaline. It is in the medulla that the sinuses are drained into the single common vein for the whole gland (see [Figure 1](#)). In the human gland there are also arteriovenous loops in which blood is apparently carried from the subcapsular arterioles in vessels which sweep down through the zona glomerulosa and the zona fasciculata, then loop back to the exterior of the gland to sites close to their origins. Also, as the vein leaves the gland, a portion of the cortex is introverted from the exterior to surround the vessel as the cortical cuff ([Figure 2](#)).

Most early studies reported that nerve fibers which entered the gland passed straight to the medulla without branching and with no evidence of nerve endings. In fact much evidence now shows that nerve fibers reach the cortex, arising partly from the medulla, but also partly through direct innervation. In general, neural arborization is most dense in the capsular and subcapsular regions and nerves may contact both adrenocortical cells and blood vessels. Both catecholaminergic and peptidergic fibers have been identified.

Hormones of the Adrenal Cortex

The hormones of the adrenal cortex are steroids: compounds that contain the *perhydrocyclopentanophenanthrene* structure consisting of four linked rings, three of six carbon atoms and one of five. There are four major groups of these compounds, classified according to the number of carbon atoms they contain.

1. C₂₇ compounds. These are the sterols, including cholesterol.

2. C₂₁ steroids. These include progesterone, the hormone of pregnancy and of female cyclic reproductive function, as well as the compounds produced more or less exclusively by the adrenal cortex. The adrenal C₂₁ steroids, collectively termed corticosteroids, are of two major types according to their

activities, the mineralocorticoids and the glucocorticoids. The activity of the mineralocorticoids is primarily concerned with the regulation of sodium and potassium homeostasis. The most potent mineralocorticoid in all mammals is aldosterone, although other corticosteroids possess some mineralocorticoid activity. The glucocorticoids were originally defined on the basis of their actions on carbohydrate metabolism but are known to have a wide variety of functions (see below). In humans and many other species (including canine, ovine, bovine) cortisol (hydrocortisone) is the most prominent secreted glucocorticoid, and smaller amounts of cortisone and corticosterone are also produced. In the rat and some other rodents (and in many nonmammalian vertebrates), adrenal 17 α -hydroxylase activity (see below) is weak, and corticosterone is the major secreted adrenocortical product.

3. C₁₉ steroids. These include the androgens, which support male structure and reproductive function. Of these, testosterone is the most potent but is normally produced in only small amounts by the adrenal. However, androstenedione, dehydroepiandrosterone (DHEA), and its sulfate (DHEAS) are prominent adrenal secretory products which may be converted to testosterone peripherally.

4. C₁₈ steroids. These include the estrogens, female sex hormones, which are not usually secreted by the adrenal. However, androstenedione and DHEA(S) from the adrenal may be converted to estrogens elsewhere and this is the major source of circulating estrogen in postmenopausal women. In the fetus, DHEAS from the fetal adrenal is converted first to 16 α -hydroxy-DHEAS and then to estriol sulfate by placental enzymes.

The circulating concentrations of the major adrenal steroids are shown in [Table 1](#).

Table 1 Examples of plasma concentrations of adrenal hormones in normal subjects^a

Steroid	Concentration
Aldosterone (pmol per L)	100–400
Androstenedione (nmol per L)	
Adults	2–13
Children	<2
Cortisol (nmol per L)	
07.00–09.00 h	280–720
21.00–24.00 h	60–340
Dehydroepiandrosterone sulfate (μ mol per L)	
Adults	2–11
Children	<2

^aValues may show considerable variations as all adrenal steroids show a diurnal rhythm, and steroid secretion may also be affected by age, nutritional status, and stage of the menstrual cycle.

Biosynthesis of the Corticosteroids

Although their biological activities may be very different (see below), the close structural similarities of the corticosteroids reflect their biosynthetic relationship. Several groups of enzymes are involved in their synthesis within the adrenal cortex, and these are summarized in [Figure 3](#) and in [Table 2](#).

Steroid hormones are formed from cholesterol. Cholesterol may be formed *de novo* from acetate in the adrenal or it may be imported into the gland from circulating low-density lipoprotein (LDL) through a process of receptor-mediated endocytosis. Cholesterol is stored as esters in the lipid droplets within the adrenocortical cell.

The rate-limiting step in these sequences is thought to be (1) the delivery of cholesterol to the inner mitochondrial membrane and CYP11A. Current evidence suggests that this is primarily facilitated by a specific protein, designated the steroidogenic acute regulatory, or StAR, protein. (2) Much evidence suggests that a second “late pathway” rate-limiting step lies between 18-hydroxydeoxycorticosterone or corticosterone and aldosterone.

However, since CYP11B2 (aldosterone synthase) can catalyze all of the steps between deoxycorticosterone and aldosterone, this could only be achieved by the regulation of the supply of the alternative precursors.

Figure 3 Pathways for biosynthesis of (a) glucocorticoids, (b) aldosterone, and (c) androgens and estrogens. The formation of aldosterone from 11-deoxycorticosterone is catalyzed by a single enzyme, CYP11B2 (aldosterone synthase). This may include the formation of other intermediates, corticosterone and/or 18-hydroxydeoxycorticosterone, that are not shown. Cortisol and, to a lesser extent, corticosterone are the major end-products of the glucocorticoid pathway, though cortisone and 11-dehydrocorticosterone (which are biologically inactive) may also be secreted. All of the dehydrogenase-catalyzed reactions may be reversible, however, i.e., cortisol may be formed from cortisone and androstenedione from testosterone.

Table 2 Enzymes involved in steroid biosynthesis

Number ^a	Type	Systematic designation	Other names	Activity
I	Cytochrome-P450	CYP11A	P-450 _{SCC}	Cholesterol side-chain cleavage
II	Dehydrogenase	3 β -Hydroxysteroid-dehydrogenase, isomerase		Conversion pregnenolone to progesterone
III	Cytochrome-P450	CYP17	P450 _{17α} , 17-hydroxylase, 17-lyase	Hydroxylation at C-17, 20 lyase (side-chain cleavage)
IV	Cytochrome-P450	CYP21	P450 ₂₁ , 21-hydroxylase	Hydroxylation at C-21
V	Cytochrome-P450	CYP11B1	P450 _{11β/18} , 11 β -hydroxylase type II	Hydroxylation at C-11 (and C-18)
VI	Dehydrogenase	11 β -Hydroxysteroid-dehydrogenase		Conversion cortisol to cortisone
VII	Cytochrome-P450	CYP11B2	Aldosterone synthase	Conversion 11-deoxycorticosterone to aldosterone (and 18-hydroxycorticosterone)
VIII	Dehydrogenase	17-Hydroxysteroid dehydrogenase		Conversion androstenedione to testosterone, estrone to estradiol and reverse
IX	Cytochrome-P450	CYP18	Aromatase	Conversion c-19 steroids (e.g., testosterone, DHEA) to estrogens

^aSee Figure 3.

Inborn errors of steroid metabolism exist which may result from congenital defects in the enzymes involved in steroid biosynthesis. A feature of all of these is that the end-product of biosynthesis (for example, cortisol) is produced in inappropriately low amounts. Accompanying this may be the excessive production of the steroid intermediate that immediately precedes the enzyme block. For example, 21-hydroxylase deficiency, the most common form, results in excessive secretion of 17 α -hydroxyprogesterone (cf. Figure 3). This has little intrinsic biological activity, though it can be converted to androgens, resulting in virilization and hirsutism. Another defect, of 11 β -hydroxylase, may result in the secretion of large amounts of 11-deoxycorticosterone, which can have profound mineralocorticoid effects, with excessive sodium retention resulting in hypertension. The lack of cortisol in these patients results in enhanced secretion of ACTH, leading both to the excessive secretion of steroid intermediates and also to the growth (hyperplasia) of the gland – hence the general term *congenital adrenal hyperplasia* or CAH. These fortunately rare conditions can usually be treated by administration of cortisol.

Knowledge of the mechanisms for corticosteroid biosynthesis have led to the development of numerous and more or less specific inhibitors of adrenal steroidogenesis. These are listed in Table 3.

Transport and Metabolism of Corticosteroids

Under normal conditions around 90% of the circulating cortisol is bound to a specific plasma binding protein, called corticosteroid binding globulin (CBG). There is no comparable plasma binding protein for aldosterone, which may be loosely bound to plasma albumin. It is generally thought that only the unbound steroid fraction is biologically active. This view has,

Table 3 Inhibitors of steroidogenesis in the adrenal cortex

Drug	Principle enzymic site of action ^a
Aminoglutethimide	CYP11A, cholesterol side-chain cleavage
Metyrapone	CYP11B1, 11 β -hydroxylase
Etomidate	CYP11B1, 11 β -hydroxylase
Trilostane	3 β -hydroxysteroid-dehydrogenase/isomerase
Ketoconazole	CYP17, 17 α -hydroxylase

^aCf. Table 2.

however, been questioned, but the conditions required for bioactivity of the bound fraction remain unclear.

The liver is the major site for corticosteroid metabolism, and in humans metabolites are generally excreted in the urine rather than by the biliary/fecal route, which predominates in some other species. The main reactions involved are reduction of ring A, hydroxylation, and conjugation as sulfates or glucuronides.

Control of Adrenocortical Secretion

Control of Cortisol Secretion

Cortisol (together with cortisone and corticosterone) is produced exclusively by the zona fasciculata and the zona reticularis of the adrenal cortex. Its secretion is almost entirely related to the degree of stimulation by circulating adrenocorticotrophic hormone (ACTH), which is secreted by the anterior pituitary gland. In the absence of ACTH (e.g., after removal of the pituitary, or hypophysectomy), glucocorticoid levels in the blood fall to about 5% of normal values within 2 h, and this fall may be reversed by administration of ACTH. Under normal conditions, cortisol secretion has a clear diurnal rhythm, paralleling the pattern of

ACTH secretion, with an early morning peak and an evening nadir. However, the secretion of ACTH is itself stimulated by all forms of stress, whatever the time of day.

Physiologically, the acute actions of ACTH are as follows: (1) to increase secretion of corticosteroids and (2) to increase blood flow through the gland. Chronically, as well as maintaining elevated glucocorticoid levels, ACTH brings about increased gland weight, which is attributable both to an increase in adrenocortical cell size and to increased blood content. Though also having some effect on cell number *in vivo*, other related pituitary peptides may stimulate adrenal mitogenesis. ACTH is also required to maintain steroid synthetic enzymes, which decline after a few days in the hypophysectomized animal. Adrenocorticotrophic hormone is also required to maintain steroid synthetic enzymes which decline after a few days in the hypophysectomized animal. Morphologically, the effects of hypophysectomy on adrenal weight are attributable to the degeneration of the zona fasciculata and zona reticularis, while the zona glomerulosa is comparatively unaffected. In the inner zones, cell numbers decline markedly (through *apoptosis*), and the remaining cells are shrunken because of major decreases in mitochondrial volume and smooth endoplasmic reticulum.

Control of Glomerulosa Function and Aldosterone Secretion

Physiologically, the most important stimuli for aldosterone secretion are altered electrolyte and fluid status (particularly sodium loss) or extracellular fluid volume reduction by hemorrhage, the use of diuretics, and postural changes: aldosterone levels are increased by upright posture. Restriction of dietary sodium intake causes hypertrophy of the zona glomerulosa and elevation of aldosterone secretion, with no concomitant effect on glucocorticoids.

The action of sodium depletion and other physiological stimulation of the zona glomerulosa is attributable to the actions of several stimulants which may act in concert. The renin-angiotensin system is especially important. This mechanism, which becomes more active when sodium intake is decreased (or sodium loss increased) or when blood volume decreases, has as its end-product the formation of a peptide hormone, called angiotensin II, which acts on zona glomerulosa cells to stimulate the secretion of aldosterone. Administered chronically, it can also reproduce the morphological changes in the zona glomerulosa which are associated with sodium depletion.

Other stimulants of aldosterone secretion include ACTH (though only transitorily) and potassium ions,

whereas the atrial natriuretic peptides (ANP) cause a decrease in circulating aldosterone concentrations.

There are numerous other factors that stimulate aldosterone secretion and zona glomerulosa function under experimental conditions, although the physiological importance of their actions remains to be clarified. These include serotonin, catecholamines, acetylcholine, vasoactive intestinal peptide, vasopressin, oxytocin, other neuropeptides, and prostaglandin E. Other inhibitors include somatostatin and dopamine.

Control of Adrenal Androgen Secretion

Adrenal androgen secretion [androstenedione and DHEA(S)] rises throughout childhood, paralleling the increase in adrenal size, and peaks just before the onset of puberty in a period that has been termed adrenarche. Secretion of these hormones remains high until 40–50 years of age, when they begin to decline (the *adrenopause*). The mechanism for regulation of adrenal androgen secretion is not completely clear, and although ACTH is a potent stimulant, the secretion of cortisol and the adrenal androgens may be dissociated under some conditions, during adrenarche, for example, when adrenal androgen secretion rises while cortisol is unchanged.

Actions of Corticosteroids

Early in the study of adrenal physiology it was discovered that this gland is essential for life because of the actions of the adrenocortical hormonal products, not those of the medulla. Among the effects of loss of adrenocortical hormones are depletion of sodium ions from the body, decreased blood volume, hypotension, increased plasma potassium levels, muscular weakness, reduced cardiac contractility, and depletion of liver and muscle glycogen together with a generally impaired capacity to respond to physical stress. It was from these beginnings that it became clear that two types of corticosteroid activity were involved. Table 4 shows the relative glucocorticoid and mineralocorticoid activity *in vivo* of some common steroids, and it can be seen that, in practice,

Table 4 Relative glucocorticoid and mineralocorticoid activity of corticosteroids

<i>Steroid</i>	<i>Mineralocorticoid activity</i>	<i>Glucocorticoid activity</i>
Aldosterone	1	0.15
Cortisol	0.001	1
Deoxycorticosterone	0.03	0.02
Corticosterone	0.004	0.4

few corticosteroids are completely specific in their effects. Thus cortisol, which normally shows about 1/1000th the mineralocorticoid activity of aldosterone *in vivo*, may have appreciable effects on electrolyte metabolism when plasma levels are elevated as in Cushing's syndrome.

Although the hormones were first classified on the basis of their physiological actions, they may also be differentiated on the basis of their binding affinity for tissue receptors. There are two main types of receptor: type I, originally detected in the kidney, was considered to be the mineralocorticoid receptor, and the more widely distributed type II receptor was thought to be responsible for glucocorticoid actions. More recently, with the cloning and characterization of the receptors, an unexpected finding has been that the recombinant mineralocorticoid (type I) receptor does not show the expected steroid specificity *in vitro* since it binds aldosterone and cortisol with equal affinity. As the levels of glucocorticoids in plasma may be up to 1000 times higher than those of aldosterone (Table 1), this raises the problem of how a specific mineralocorticoid effect can be exerted in the intact animal. Currently, it is believed that the presence of 11 β -hydroxysteroid dehydrogenase type II (cf. Figure 3a and Table 2) in mineralocorticoid target tissues explains this paradox. The enzyme converts glucocorticoids to their 11-keto derivatives (cortisone and 11-dehydrocorticosterone), which do not bind effectively to the receptor. In this way, the receptor is protected, and cortisol and corticosterone do not cause sodium retention at normal physiological levels. Conversely, the type I enzyme, which catalyses the reverse reaction, thus converting cortisone to cortisol, may enhance local availability of cortisol.

Mineralocorticoid Actions

The main actions of hormones which bind to type I (mineralocorticoid) receptors are to increase the reabsorption of sodium in the kidney and at other secretory epithelial sites, thus reducing the sodium content of urine, sweat, saliva, and so on. Effectively, sodium ions are exchanged for hydrogen and potassium ions, leading to decreased sodium and increased potassium excretion and increased urine acidity. With prolonged mineralocorticoid treatment, extracellular fluid volume expansion occurs, but after a few days the kidney escapes from the mineralocorticoid effect on sodium but not potassium excretion, and thus a major effect of prolonged mineralocorticoid exposure is that body potassium levels are reduced. Hypertension (high blood pressure) is a well-known consequence of excess corticosteroid secretion and is seen in conditions with elevated aldosterone secretion such

as Conn's syndrome as well as in conditions of elevated cortisol secretion such as Cushing's syndrome. The mechanisms by which steroids increase blood pressure is not fully understood. In both old age and chronic illness, there is also a dissociation between circulating cortisol and DHEA, with cortisol remaining unchanged, or decreasing, while DHEA secretion declines.

Glucocorticoid Actions

The effects of glucocorticoid receptor activation are varied and complex. Almost all tissues of the body have been found to contain type II receptors and a very large number of systems and processes are affected by these steroids. They are essential for the maintenance of cardiovascular and metabolic homeostasis, particularly during physically stressful conditions. In addition, they play a role in modulating inflammatory and immune responses and affect central nervous system function. In the perinatal period, glucocorticoids are particularly important in controlling lung development and maturation, which may present particular problems in premature infants who have not been sufficiently exposed to glucocorticoid.

The major metabolic effects of glucocorticoids are the stimulation of protein catabolism and hepatic glycogen synthesis. The actions essentially oppose those of insulin and are most evident in the unfed state. General inhibition of protein synthesis may be partly responsible for the inhibition of growth caused by corticosteroid administration to young subjects.

In general, glucocorticoids exert powerful suppressive effects on the immune and inflammatory systems, and synthetic glucocorticoids are widely used to control the symptoms of many inflammatory and autoimmune diseases. These effects seem to be produced through the ability of the hormones and drugs to inhibit the production and actions of the cytokines that mediate the responses. Paradoxically, however, it has recently been recognized that endogenous corticosteroids may also augment some aspects of the immune response.

Corticosteroids can freely cross the blood-brain barrier and exert complex effects on behavior. Approximately 70% of patients with Cushing's syndrome are reported to be depressed; in contrast, treatment with exogenous glucocorticoid is commonly associated with improved mental state.

Stress

The relationship between increased adrenocortical activity and stresses of many different types has been known since the 1930s, and levels of cortisol in plasma are frequently measured as an index of stress.

However, the mechanisms through which glucocorticoids confer resistance to stress is still debated. There is general agreement that the actions of glucocorticoids in the cardiovascular system which increase vascular reactivity and improve cardiac performance are beneficial under acutely stressful conditions. However, in the past it was often considered that the suppressive effects of glucocorticoids on the inflammatory and immune systems could not be rationalized in the context of protection against stress. More recently it has been suggested that glucocorticoids, by virtue of their ability to suppress the response to infection and injury, may protect against the overreaction of these systems and the risk of excessive vasodilatation, edema, and other damaging effects. The corollary of this is that an inadequate adrenocortical response to stress may be harmful in that defence reactions will proceed unchecked. This may be true of some patients; for example, in active rheumatoid arthritis or, possibly, in chronic fatigue syndrome. In some senses, glucocorticoids appear to regulate defence mechanisms in two opposing ways. In their permissive mode (at levels found in the normal diurnal cycle) the hormones act to prime the body for normal activity, whereas the suppressive effects (at levels found during severe stress) prevent overreaction.

Chronic excess of glucocorticoids also has deleterious effects on the organism. This is most obvious in Cushing's syndrome, the symptoms of which include depression, hypertension and cardiovascular disease, osteoporosis, immunosuppression, visceral obesity, insulin resistance, and metabolic abnormalities. It has also been argued that more subtle forms of exposure to increased levels of corticosteroids such as might be experienced in chronic psychosocial stress could increase susceptibility to infection and tumors and be associated with severe depression and aging-related memory impairment.

Definition and Etiology of Adrenal Insufficiency

Clinical Presentation and Diagnosis

Treatment

Additional Aspects and Implications for Stress

Glossary

<i>Adrenal crisis</i>	Acute manifestation of adrenal insufficiency with symptoms including hypotension, hypovolemic shock, fever, and/or hypoglycemia. This condition is a medical emergency.
<i>Adrenal insufficiency</i>	Characterized by hypocortisolism and/or hypoaldosteronism. See also Primary adrenal insufficiency, Secondary adrenal insufficiency, and Tertiary adrenal insufficiency.
<i>AIDS</i>	Acquired immunodeficiency syndrome.
<i>Cushing's disease</i>	State of chronic hypercortisolism due to increased secretion of corticotropin from pituitary adenomas. See also Cushing's syndrome.
<i>Cushing's syndrome</i>	State of chronic hypercortisolism in general with typical clinical features. See also Cushing's disease.
<i>Primary adrenal insufficiency</i>	State of hypocortisolism and/or hypoaldosteronism due to a pathologic process that involves the adrenal glands in the first place. See also Secondary adrenal insufficiency and Tertiary adrenal insufficiency.
<i>Secondary adrenal insufficiency</i>	State of hypocortisolism and/or hypoaldosteronism due to a diminished capacity of the pituitary gland to secrete corticotropin. See also Primary adrenal insufficiency and Tertiary adrenal insufficiency.
<i>Sheehan's syndrome</i>	Pathologic condition of a newborn characterized by intrapituitary postpartum hemorrhage.

Tertiary adrenal insufficiency

State of hypocortisolism and/or hypoaldosteronism due to a pathologic process that involves the hypothalamus in the first place. See also Primary adrenal insufficiency and Secondary adrenal insufficiency.

Definition and Etiology of Adrenal Insufficiency

Adrenal insufficiency (AI) is a heterogeneous group of diseases leading to a functional impairment of the hypothalamic-pituitary-adrenal (HPA) axis ([Table 1](#)). Adrenal insufficiency is caused by a disease process located in the adrenal glands (primary), the pituitary (secondary), or the hypothalamus (tertiary) and describes a state of glucocorticoid deficiency, mineralocorticoid deficiency, or deficiency in adrenal androgen production. Depending on the lesion that causes the adrenal hypofunction, isolated or combined impairment of adrenal hormone secretion may ensue.

Primary adrenal insufficiency was first described by Thomas Addison one and half a centuries ago; therefore, all primary forms of this condition are also termed Addison's disease. Because clinical symptoms usually do not occur until more than 90% of the adrenal cortex is destroyed or nonfunctional, both organs have to be affected.

The autoimmune destruction of the adrenal glands is the most common cause of primary adrenal insufficiency in the industrialized world, accounting for the majority of cases. Autoimmune adrenalitis can occur isolated or in combination with other autoimmune diseases ([Table 2](#)). Combinations are termed autoimmune polyendocrinopathy syndrome (APS). The monogenetic form of this syndrome, autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy (APECED, APS type I), is due to mutations in the autoimmune regulatory (AIRE) gene located on chromosome 21q22.3 and usually develops early in life. APS type II, which is also called Schmidt's syndrome when Addison's disease and hypothyroidism are present, is a complex genetic disorder and often occurs spontaneously. Susceptibility to developing this disease is conferred by genes in the human leukocyte antigen (HLA) region on the short arm of chromosome 6, and different susceptibility and resistance alleles of the major histocompatibility complex (MHC) class II

Table 1 Etiology of adrenal insufficiency^a

Primary adrenal insufficiency	Autoimmune (idiopathic) disease	
	Expansive disease	Infection (tuberculosis, fungi) Hemorrhage (sepsis, anticoagulants, trauma) Secondary tumor (metastasis)
	Congenital-hereditary diseases	Congenital adrenal hyperplasia Congenital adrenal hypoplasia Congenital unresponsiveness to ACTH X-linked adrenoleukodystrophy / adrenomyeloneuropathy
Secondary and tertiary adrenal insufficiency	Drugs	Inhibitors of steroidogenesis Adrenolytic agents Glucocorticoid antagonists
	Glucocorticoid withdrawal syndrome	Following glucocorticoid therapy
	Expansive disease	Following neurosurgery Primary or secondary tumor, infection (tuberculosis) Inflammation (autoimmune, sarcoidosis)
	Iatrogenic hypopituitarism	following surgery, following radiation
	Other	Postpartum hemorrhage (Sheehan's syndrome) Trauma Apoplexy
Isolated hypoadosteronism		Hyporeninism Surgery Congenital-inherited biosynthetic defect
		Central diseases Prolonged heparin treatment
		Tuberculosis
Isolated adrenomedullary insufficiency		Infiltration by tumors Surgery Congenital-inherited dysautonomia

^aACTH, adrenocorticotrophic hormone.**Table 2** Clinical manifestations of autoimmune polyendocrinopathy syndromes

Autoimmune endocrine diseases	Autoimmune adrenalitis, Autoimmune thyroid disease Autoimmune hypergonadotropic hypogonadism
	Type 1 diabetes mellitus Chronic hypoparathyroidism Autoimmune hypophysitis
Autoimmune diseases of other tissues	Skin/ectodermal manifestations: chronic mucocutaneous candidiasis, vitiligo, alopecia, nail dystrophy, keratoconjunctivitis, enamel dysplasia
	Chronic atrophic gastritis with: pernicious anemia, hypergastrinemia with benign carcinoids
	Celiac disease with malabsorption
	Autoimmune hepatitis

have been identified so far. Other candidate genes include the cytotoxic T-lymphocyte antigen 4 (CTLA4) coding region of chromosome 2 on q33.

Hereditary or congenital adrenal dysfunction is particularly important in the pediatric patient population and is in the majority of cases due to

deficiencies of enzymes involved in adrenal steroidogenesis, of which defects in the CYP21 enzyme gene are the most frequent. Depending on the site and number of hits to the alleles that encode for the steroidogenic cytochromes, different enzyme activities with different phenotypes result. Of these, the salt-wasting forms are the most severe and life-threatening conditions of congenital adrenal hyperplasia (CAH). In puberty and adults, hirsutism, irregularities in the menstrual cycle, acne, or hair loss may point to a heterozygous form of this condition.

Adrenal hypoplasia congenita (AHC) can occur in an X-linked trait due to a mutation of the DAX-1 gene. Hypogonadotropic hypogonadism or premature puberty can be combined with this disorder or represent the only clinical presentation. Isolated glucocorticoid deficiency, triple A syndrome, and the demyelinating X-linked lipid metabolism disorders adrenoleukodystrophy and adrenomyeloneuropathy are also forms to be considered in the workup of Addison's disease.

The destruction of the adrenal cortex can also be the consequence of chronic infectious diseases. Tests of adrenocortical reserve are frequently impaired in chronic systemic diseases, including tuberculosis, acquired immunodeficiency syndrome

(AIDS), toxoplasmosis, histoplasmosis, sarcoidosis, and amyloidosis. Bilateral metastatic infiltration or intraadrenal hemorrhage due to sepsis (*Meningococcus*) or anticoagulation are rare. However, postprimary tuberculosis still accounts for approximately 10% of the cases in the industrialized world and the majority of cases with a low standard of living. This condition is usually complicated by the involvement of other organ systems. Nonetheless, autoimmune adrenalitis may occur in cases with tuberculosis too. Of the fungal infections that are also known to cause adrenocortical dysfunction, histoplasmosis is common. Other causes of primary adrenal insufficiency have a rather low prevalence.

Iatrogenic forms of primary adrenal insufficiency include bilateral adrenalectomy and treatment with glucocorticoid receptor antagonists, such as RU486 (mifepristone); adrenolytic agents, such as mitotane and suramin; and drugs that inhibit steroidogenesis, such as ethomidate, aminoglutethimide, metyrapone, ketoconazole, and trilostane.

Secondary adrenal insufficiency due to a diminished secretion of corticotropin is frequent. Iatrogenic suppression of the HPA axis or adrenal suppression in the course of glucocorticoid treatment and subsequent discontinuation is the most common cause. Also, adrenal suppression is observed in patients with endogenous Cushing's syndrome after correction of the hypercortisolism by curative surgery. Other iatrogenic causes of secondary adrenal insufficiency include hypopituitarism following surgical intervention for pituitary and hypothalamic tumors and radiation. Space-occupying lesions in the hypothalamic-pituitary area (e.g., pituitary adenomas, craniopharyngiomas, meningiomas, or even metastatic infiltration and vascular lesions) may result in hypopituitarism. In addition, trauma, Sheehan's syndrome (intrapituitary postpartum hemorrhage) and apoplexy are also possible causes of impaired pituitary-adrenocortical function. Rare conditions include hypophysitis and granulomatous disorders affecting the pituitary gland.

Usually, secondary forms of adrenal insufficiency are limited to glucocorticoid deficiency in both sexes and androgen deficiency in women.

Tertiary adrenal insufficiency is a rare form of adrenal insufficiency. Main causes include hemorrhage due to trauma, tumorous formations, and ischemia in the hypothalamus. In addition, the hypothalamus is also a site for the endocrine feedback regulation by glucocorticoids and, therefore, is involved in iatrogenic adrenal insufficiency, as already described.

Some disease states of unknown pathophysiology, such as posttraumatic stress disorder, chronic fatigue syndrome, and fibromyalgia, may also be associated with dysfunction of the HPA axis resulting in

hypo- or hypercortisolism. Guidelines for the diagnosis and therapy of these controversially discussed conditions are under development. Psychological care, introduction into self-help groups, and symptomatic treatment are current therapeutic approaches.

In addition, there are disorders that cannot be classified within this scheme and are named relative adrenal insufficiency. In critical illness (e.g., sepsis and shock), it has been found that patients demonstrated high levels of corticotropin and cortisol. However, it has been shown that glucocorticoid therapy is beneficial in the survival for this subgroup of patients. Therefore, it has been suggested that the elevation of corticotropin in critical illness reflects a state of relative hypocortisolism. The elevation of inflammatory cytokines and presence of bacterial toxins cause a profound activation of the HPA axis and are believed to contribute to the development of relative adrenal insufficiency.

Clinical Presentation and Diagnosis

The main clinical manifestations of adrenal insufficiency are caused by hypocortisolism and hypoaldosteronism. All forms of adrenal insufficiency may present as an acute adrenal crisis or as chronic state with exacerbations. Acute symptoms include anorexia and/or vomiting, somnolence, orthostatic or persistent hypotension with dizziness, hypovolemic shock, fever, and hypoglycemia. Adrenal crisis is a medical emergency.

Patients with chronic adrenal insufficiency may present with weakness, failure to thrive (children), weight loss, anorexia, fatigue, nausea and vomiting, orthostatic hypotension, and abdominal pain. In primary adrenal insufficiency, lack of negative pituitary and hypothalamic feedback by glucocorticoids causes increased secretion of adrenocorticotrophic hormone (ACTH), which has melanocyte-stimulating activity causing hyperpigmentation (creases of palms, buccal mucosa, breast areolas and nipples, and scars). In most forms of congenital adrenal hyperplasia, hyperandrogenism (virilization of girls and premature puberty of boys and girls) is observed. In combined glucocorticoid and mineralocorticoid deficiency, relative hypovolemia leads to compensatory secretion of antidiuretic hormone with resulting hyponatremia, whereas the lack of aldosterone leads to salt loss and retention of potassium and protons. The rare forms of defective 17 α -hydroxylation lead to glucocorticoid and androgen deficiency in combination with mineralocorticoid excess.

An adrenal crisis can be diagnosed on the basis of a single cortisol measurement at the time of crisis.

Low serum sodium concentrations in combination with hyperkalemia and elevated plasma renin and ACTH concentrations strongly suggest primary adrenal insufficiency, whereas elevated serum potassium levels are not typical for secondary forms of hypocortisolism. Hypoglycemia may occur in children, women, and very thin men. Lymphocytosis with eosinophilia, azotemia, and metabolic acidosis may be present, and the first results in the diagnostic workup. Routine laboratory parameters may demonstrate no abnormalities in early adrenal hypofunction. Specific study methods to ensure and further differentiate the diagnosis of adrenal insufficiency should not delay therapeutic intervention during an adrenal crisis.

Adrenal stimulation tests provide evidence of a dysfunction of the HPA axis. Among them the rapid (60-min) corticotropin test is useful for the diagnosis of adrenal insufficiency, whereas the corticotropin releasing hormone (CRH) test and the long 48-h ACTH stimulation tests are useful for the differentiation of primary and secondary adrenal insufficiency (Table 3). Although basal cortisol production may be normal, an impaired increase in steroid output may be present and difficult to diagnose. Therefore, these tests, particularly the fast one, are valuable tools in establishing the diagnosis of adrenal hypofunction in cases of decreased adrenal reserve and in monitoring the recovery of the HPA axis after the discontinuation of glucocorticoid therapy or correction of hypercortisolism.

In several countries, screening for congenital adrenal hyperplasia and genetic workup of heterozygous patients have been shown to decrease the risk of early death and to be cost-effective in health programs.

Autoantibodies can develop and are detectable in most cases of autoimmune adrenalitis. They are directed against CYP21, CYP11 β , CYP17, or steroidogenic cells and more frequent in APS type I or II than in isolated autoimmune adrenalitis. In autoimmune polyendocrinopathy syndromes without adrenal insufficiency, they allow the prediction of a possible manifestation of this complication in 85% of patients.

Treatment

The therapeutic goal is an optimal replacement of glucocorticoids and, if necessary, mineralocorticoids. In addition, there is need of an additional glucocorticoid substitution therapy in certain stress-related circumstances. Therefore, all patients with this condition and their close relatives and friends need careful education about the management of their disease and should be handed out an Emergency Health Card, containing information on disease, regimen of hormone substitution and instructions how to avoid or deal with an adrenal crisis.

Usually, patients do very well with oral glucocorticoids. The treatment of choice is hydrocortisone. Doses of 10–20 mg in the early morning may be sufficient, especially in cases with mild secondary adrenal insufficiency. However, in primary forms or complete secondary hypocortisolism, 10–15 mg/m²/day may be necessary. To simulate the circadian rhythm of glucocorticoid secretion split, doses are given: two-thirds in the morning and one-third in the afternoon (Table 4). Before surgery or dental extraction or during periods of intercurrent illness, steroid dosage has to be doubled or even tripled. During severe stress (such as

Table 3 Differentiation among primary, secondary, and tertiary adrenal insufficiency^a

Table 4 Examples of glucocorticoid replacement therapy

Glucocorticoid	Morning	Noon	Late afternoon
Hydrocortisone ^a	15 mg	10 mg	5 mg
Cortisone acetate	25 mg	—	12.5 mg
Prednisone	5 mg	—	—

^aHydrocortisone is recommended.

car accidents, sepsis, or major surgery), an individual's intact adrenal gland will increase its cortisol secretion approximately fivefold. Therefore, during such situations, replacement doses higher than 200 mg day⁻¹ are not required in patients with adrenal insufficiency. Following an operation, provided that there are no complications, the hydrocortisone doses should be returned to the normal replacement regimen within a few days. Parenteral administration may be required. Although cortisol and cortisone have mineralocorticoid effects, a dose of 30 mg day⁻¹ covers only approximately 50% of the daily requirement. Therefore, 0.05–0.1 mg fludrocortisone, a synthetic mineralocorticoid, is given to Addisonian patients. Furthermore, these patients should be put on a sodium-enriched diet because they are frequently not able to conserve this electrolyte in spite of replacement therapy.

Adrenal insufficiency may lead to a deficit in androgen secretion in women. The substitution of dehydroepiandrosterone in women with this disorder has been proven beneficial and is being considered for inclusion in the treatment regimen. Women with secondary or tertiary forms of adrenal insufficiency may be put on hormone replacement therapy with estrogens and a gestagen, which has a partial androgenic action.

In some cases of secondary and tertiary adrenal insufficiency, such as in dermatomyositis and multiple sclerosis, treatment with corticotropin may be more effective than glucocorticoid therapy. In fact, the administration of corticotropin leads to the secretion of adrenal androgens, glucocorticoids, and mineralocorticoids and generally prevents the adrenal glands from hypotrophy but not the hypothalamic-pituitary unit from suppression. Oral glucocorticoid replacement is generally sufficient and easier to adjust to the individual's requirements in the great majority of the patients.

In acute adrenocortical insufficiency, therapy should be initiated immediately after taking blood for the determination of cortisol and corticotropin levels. Hypovolemic shock requires the rapid replacement of sodium and water deficits. This is accomplished by the intravenous infusion of 5%

glucose in normal saline solutions lacking potassium. Cortisol should be administered, starting with a bolus of 100 mg. An adrenal crisis is often precipitated by acute stress. Therefore, an appropriate increase in glucocorticoid replacement serves to restore glucocorticoid function. After successful treatment and improvement of the patient's condition, glucocorticoids can be administered orally and the doses can be lowered to maintenance levels. (The treatment of the different forms of congenital adrenal hyperplasia are not discussed in this article.)

Additional Aspects and Implications for Stress

Glucocorticoids do not participate only in endocrine feedback loops with corticotropin and CRH at the levels of the pituitary gland and the hypothalamus, respectively, but also in feedback loops with other peptides derived from the immune system. Of those mediators, interleukin-6 is a key interface between the immune system and the HPA axis. This cytokine is found to be elevated in patients with hypocortisolism and believed to play a role in the steroid withdrawal syndrome.

Glucocorticoids are associated with a switch in production from T helper cell (Th)1 to Th2 cytokines. The absence of glucocorticoids leads to an enhanced Th1 profile, promoting autoimmune and allergic phenomena, including autoimmune thyroid disease, rheumatoid arthritis, and asthma.

Adrenal insufficiency is a state of hypocortisolism and, thus, is a decreased effectiveness of the adaptive response. The profound dysregulation of the HPA axis with loss of drive (secondary and tertiary forms) or loss of feedback (primary forms) makes a balanced homeostasis impossible. Therefore, frequently, manifestations of adrenal insufficiency are observed under stressful conditions, such as inapparent infection, physical challenge, and surgery. Once the diagnosis of adrenal insufficiency has been established, careful diagnosis and causal therapy of a possible underlying disease are also pivotal.

When Brown-Sequard and Thomas Addison recognized that the adrenal glands were organs necessary for life, they did not have knowledge of Hans Selye's concept of stress. Adrenal dysfunction practically means the disintegration of the powerful stress system, which is necessary for maintenance of homeostasis. Cases of adrenal insufficiency document the importance of such a system. Its dysfunction may result in severe life-threatening disorders.

Summary and Conclusion

Glossary

Adrenal medulla

The inner portion of the adrenal gland that is part of the sympathetic-adrenal medullary system. The adrenal medulla receives neural input from sympathetic preganglionic fibers arising from the intermediolateral cell column of the thoracic and lumbar regions of the spinal cord. It is known primarily for its ability to synthesize and secrete the stress hormone epinephrine.

Chromaffin cell

The cell type that makes up the bulk of the adrenal medulla, named for its capacity to take up and stain with chromium salts. In most mammalian species, there are two types of chromaffin cells: those that synthesize, store, and secrete norepinephrine and those that synthesize, store, and secrete epinephrine. These cells also synthesize, store, and

secrete a range of biologically active peptides.

Dopamine-β-hydroxylase (DBH)

An enzyme, contained within vesicles, that catalyzes the conversion of dopamine to norepinephrine.

Neuropeptide Y (NPY)

A 36-amino-acid peptide found in cell bodies and nerve terminals of the central and peripheral nervous systems. This peptide is also localized within chromaffin cells of the adrenal medulla as well as other nonneuronal cells. It has important effects on the cardiovascular system and is also a smooth muscle cell mitogen.

Phenylethanolamine N-methyltransferase (PNMT)

An enzyme localized within epinephrine-containing chromaffin cells of the adrenal medulla, adrenergic neurons of the central nervous system, and some other peripheral tissues (e.g., the heart). This enzyme catalyzes the conversion of norepinephrine to epinephrine.

Tyrosine hydroxylase (TH)

An enzyme localized to catecholamine-synthesizing cells that catalyzes the conversion of tyrosine to dihydroxyphenylalanine. The hydroxylation of tyrosine is the rate-limiting step in catecholamine biosynthesis.

The adrenal medulla played a pivotal role in studies of the physiology of stress for most of the twentieth century. As the nineteenth century came to a close, the pharmacologist John Jacob Abel of Johns Hopkins University identified epinephrine (EPI) as the endogenous substance from the adrenal gland with pronounced effects on the cardiovascular system. Soon thereafter, Takamine identified the chemical structure and the synthesis of EPI was described. EPI was the first hormone with a known chemical structure. The physiologist Walter Branford Cannon of Harvard University conducted a series of seminal experiments

on the importance of the adrenal medullary secretion of epinephrine during various types of stressful stimulation in animals and humans. Based on these studies, he introduced the terms homeostasis and fight-or-flight into the scientific literature, and these terms remain in use to the present. Another catecholamine, norepinephrine (NE), was identified in the middle of the twentieth century by Ulf S. von Euler of Karolinska University in Sweden as the neurotransmitter in sympathetic nerves.

The adrenal medulla of many mammalian species, including rats and humans, has both NE-containing and EPI-containing secretory cells. These two types of adrenal chromaffin cells are innervated by sympathetic preganglionic fibers of the splanchnic nerve. Each chromaffin cell contains approximately 10–30 thousand chromaffin granules in which catecholamines (CAs) are stored. Human adrenals contain approximately 6 mg of CAs (the ratio EPI : NE is approximately 4 : 1). The secretion of CAs from adrenal medullary chromaffin cells is controlled in part by the sympathetic preganglionic nerve fibers, and the CAs, secreted via exocytosis, are carried from the site of release by blood that drains from the adrenal medulla and into the adrenal vein. NE and EPI are then carried throughout the body (with the exception of those portions of the central nervous system where the blood–brain barrier is intact) and exert effects on most of the major organ systems of the body.

Biosynthesis and Release of Adrenal Medullary Catecholamines

The CA biosynthetic pathway is summarized in [Table 1](#). CAs are synthesized from the amino acid precursor tyrosine. There are two primary sources of tyrosine: the diet and hydroxylation of the amino acid phenylalanine in the liver.

On entry into an adrenal chromaffin cell, tyrosine is converted to dihydroxyphenylalanine (DOPA) by the soluble cytoplasmic enzyme tyrosine hydroxylase (TH). TH activity is regulated in part by concentrations of Fe²⁺, O₂, Mg²⁺, adenosine triphosphate

(ATP), and the cofactor tetrahydrobiopterin. Under most conditions, TH is the rate-limiting step in CA biosynthesis. DOPA is converted into dopamine (DA) by a nonspecific enzyme, aromatic amino acid decarboxylase (AADC). AADC activity depends on levels of its cofactor pyridoxal phosphate. DA is taken up into storage vesicles and converted to NE by dopamine-β-hydroxylase (DBH), an enzyme found in soluble and membrane-bound forms within storage vesicles. DBH activity is influenced by levels of copper, ascorbic acid, and O₂. NE is then converted to EPI by the soluble cytoplasmic enzyme phenylethanolamine N-methyltransferase (PNMT), which uses S-adenosyl-methionine as the cofactor.

Separate populations of adrenal chromaffin cells contain NE and EPI as the final products of CA biosynthesis. The latter are distinguished from the former by the presence of PNMT. Under resting conditions, low levels of EPI (but very little NE) are released into blood from the adrenal medulla. During some types of stressful stimulation, however, significant amounts of NE may be released from the adrenal medulla and may compose up to 35% of the total circulating NE. The remaining 65% of NE is released from sympathetic nerve terminals and enters blood from the site of release at the neuroeffector junction.

As already mentioned, NE and EPI are stored in chromaffin granules that are formed from the Golgi apparatus and enclosed by a single membrane. The chromaffin granules contain water, various proteins, ATP, and lipid, in addition to either NE or EPI. The most prominent proteins include the chromogranins. The release of CAs together with other compounds from adrenal chromaffin cells is via exocytosis.

Until the mid-1980s, the view of the adrenal medullary system was relatively simplistic. Acetylcholine was released from sympathetic preganglionic nerve terminals and bound to nicotinic cholinergic receptors on the adrenal chromaffin cells. The interaction of acetylcholine with its nicotinic receptor led to a depolarization of the chromaffin cell membrane, resulting in an increase in membrane permeability to sodium. Increased intracellular sodium initiated a series of events that led to an increase in the influx of calcium. Amine storage vesicles fused with the chromaffin cell membrane and released their contents of EPI or NE via exocytosis. Although it was known in the mid-1980s that chromogranins, ATP, and a fraction of the soluble DBH were released during exocytosis, the focus of attention was on EPI and its biological effects.

Since the mid-1980s, a wealth of new information has accumulated and the adrenal medulla can no longer be viewed as a tissue that is under the exclusive control of acetylcholine and concerned primarily with the synthesis, storage, and secretion of CAs ([Table 2](#)).

Indeed, more than 30 biologically active substances have been localized to adrenal chromaffin cells, and a number of them have been shown to be released following depolarization of the chromaffin cell membrane. In addition, various biologically active neuropeptides are colocalized with acetylcholine within sympathetic preganglionic nerve terminals. Several of these neuropeptides, including substance P, NPY, vasoactive intestinal peptide (VIP), and pituitary adenylate cyclase-activating polypeptide (PACAP), appear to act as neuromodulators of cholinergic transmission. Finally, chromaffin cells have a range of membrane-bound receptors for various biologically active molecules that are released from preganglionic nerve terminals or are delivered to chromaffin cells via the circulation. These substances may also interact in complex ways to regulate secretory patterns of adrenal chromaffin cells. Each chromaffin cell may also have its own secretory phenotype based on the complement of peptide and classical neurotransmitter receptors contained on its outer cell membrane.

In some instances, peptides released from adrenal chromaffin cells may exert negative feedback effects on continued chromaffin cell secretory activity by stimulating chromaffin cell receptors. This type of intramedullary feedback loop introduces a new layer

of complexity to the regulation of adrenal medullary secretion.

Stress Effects on the Biosynthetic Capacity of the Adrenal Medulla

Plasma Epinephrine and Stress

Many different approaches have been taken to assess the functional status of the adrenal medulla. Beginning in the 1950s, fluorometric assays of CAs were employed to study the effects of stress on whole gland content of EPI and NE. In addition, fluorometric assays allowed for quantification of urinary excretion rates of CAs in laboratory animals and in humans. The earliest studies of plasma levels of CAs also made use of fluorometric assays. However, studies of plasma CAs in laboratory animals and in humans were greatly facilitated by the introduction of highly sensitive radioenzymatic thin-layer chromatographic techniques in the 1970s and high-pressure liquid chromatography with electrochemical detection (HPLC-EC) beginning in the 1980s.

Studies of plasma levels of EPI revealed a number of facets of adrenal medullary regulation. The adrenal medulla is for all intents and purposes the sole source of circulating EPI in all mammalian species that have

been studied, including humans. Gene expression of PNMT and levels of PNMT protein have also been detected in several other organs such as the heart, spleen, thymus, and some brain-stem nuclei. However, EPI synthesized in these tissues has mainly a local function and practically does not influence the EPI concentration in circulation. In all studies dealing with levels of circulating EPI and NE, the subjects must be surgically prepared with indwelling arterial or venous catheters to reduce to the greatest extent possible any stress associated with blood collection. Basal plasma levels of EPI in laboratory rats and in humans are often less than 50 pg ml^{-1} . Plasma EPI levels increase rapidly in response to even minor stressors, and there is a monotonic relationship between the intensity of a stressor and the increment above the baseline in plasma levels of EPI.

Prior stress history exerts a profound effect on the secretory response of the adrenal medulla to subsequent exposure to a stressor. For example, if a laboratory rat is exposed to the same stressor each day for several weeks, the adrenal medullary response to the next exposure to that same stressor is reduced significantly compared to first-time-stressed controls. In contrast, if these same chronically stressed animals are instead exposed to a novel stressor, the adrenal medullary response is significantly greater compared to a first-time-stressed control group. The former pattern has been referred to as habituation, and the latter response has been referred to as sensitization. The mechanisms explaining these effects are not fully understood even if changes in gene expression of CA-synthesizing enzymes are in a good correlation with changes in CA secretion. However, it has been assumed that splanchnic stimulation of the adrenal medulla is reduced during the development of habituation and is enhanced during a sensitizing experience.

An important research question since the late 1960s has been the processes by which the adrenal medulla responds to acute versus chronic intermittent exposure to stressful stimulation. This research question has been subject to ongoing refinement as new and more sensitive neurochemical and molecular biological techniques have become available. Most of the studies in this field of inquiry have focused on regulatory processes affecting CA biosynthesis and release. However, although the adrenal medulla secretes a complex array of biologically active peptides, many fewer studies have examined how the biosynthesis and release of these neuropeptides are affected by chronic intermittent stress and exposure to novel stressors.

Exposure to a single episode of immobilization stress for up to 2 h is attended by a significant decrease of 15–20% in the total adrenal medullary content of EPI. An animal or human experiencing this

sustained exposure to an acute stressor does not know when the stressor will be terminated and, once terminated, if and when the stressor will begin again. In the face of this uncertainty, how does the adrenal medulla meet the immediate needs of replenishing supplies of EPI in adrenal chromaffin cells and what, if any, provisions are made for an uncertain future?

Given that the synthesis of EPI within the adrenal medulla involves a complex interplay of several different enzymes, studies have focused on three key enzymes: TH, DBH, and PNMT. Recently, these enzymes were intensively studied at the level of their gene transcription and translation to protein, as well as the regulation of these processes by transcription factors. The most extensive literature is available for TH because of its role as the rate-limiting step in CA biosynthesis; however, the other two enzymes have also received considerable attention. The discussion here focuses in large part on the effects of acute versus repeated immobilization stress in laboratory rats because there is an extensive literature relating to this stressor and the studies have been performed in a systematic fashion.

Effects of Acute Immobilization Stress on Adrenal Catecholamine Synthesizing Enzymes

Following a single 2-h period of immobilization stress, there are profound changes in mRNA levels of adrenal biosynthetic enzymes but very little change in enzyme activity and protein levels. Compared to values in unstressed controls, TH mRNA levels increase by approximately 600%, DBH mRNA levels increase by approximately 100%, and PNMT mRNA levels increase by approximately 200% (Table 3). In contrast, following a single 2-h period of immobilization stress TH, DBH, and PNMT enzyme activities and protein levels do not change significantly. Note here the dissociation between the levels of message for the CA biosynthetic enzymes versus the actual levels of enzyme activity. Note, too, that increases in DBH mRNA levels are just as likely to not be increased significantly following a single episode of immobilization stress.

Table 3 Adrenal mRNA levels (in arbitrary units) of TH, DBH, and PNMT under basal conditions and immediately and 24 h following one 2-h period of immobilization stress

Enzyme	Baseline	Post-IMMO	24 h post-IMMO
TH	1.00 ± 0.21	$7.50 \pm 0.50^{**}$	1.60 ± 0.25
DBH	1.00 ± 0.10	$1.88 \pm 0.49^{*}$	1.42 ± 0.50
PNMT	1.00 ± 0.32	$3.00 \pm 0.33^{**}$	1.52 ± 0.20

Values are means $\pm$ SEM. * indicates $P < 0.05$ and ** indicates $P < 0.01$ compared to unstressed controls. DBH, dopamine- β -hydroxylase; IMMO, immobilization stress; PNMT, phenylethanolamine-N-methyltransferase; TH, tyrosine hydroxylase.

These changes in mRNA levels for adrenal CA-synthesizing enzymes following a single period of immobilization stress are transient and reach the peak levels 3 h after the immobilization is completed. Twenty-four hours following a single 2-h period of immobilization stress, mRNA levels for TH, DBH, and PNMT return toward baseline levels and are no longer significantly different from unstressed control levels (Table 3).

Recently, methods for quantitative evaluation of gene expression of CA biosynthetic enzymes became available. Kvetnansky and coworkers for the first time quantified basal and stress-induced concentrations of TH, DBH, and PNMT mRNA in rat adrenal medulla, sympathetic ganglia, and various brain nuclei by the reverse transcription (RT)-competitive polymerase chain reaction (PCR) method using corresponding competitors of known concentration.

In the adrenal medulla, the basal concentration of TH mRNA was approximately 0.5 amol ng^{-1} of total RNA. DBH mRNA was approximately 12 times higher (6.0 amol ng^{-1} RNA) and PNMT mRNA was approximately 56 times higher ($28.0 \text{ amol ng}^{-1}$ RNA) than TH mRNA. In the stellate ganglia, the basal concentration of TH mRNA was approximately 30 times lower than in the adrenal medulla, but the concentration of DBH mRNA in the ganglia was similar to the adrenal medulla. Unexpectedly, the presence of a low level of PNMT mRNA has been detected for the first time in the sympathetic ganglia of rats.

Immobilization stress produced approximately a sixfold increase of TH mRNA (3.0 amol ng^{-1} RNA), a 2.5-fold increase of DBH mRNA ($15.0 \text{ amol ng}^{-1}$ RNA), and approximately a fivefold increase in PNMT mRNA ($140.0 \text{ amol ng}^{-1}$ RNA), in spite of the fact that basal levels of PNMT mRNA were already very high. Twenty-four hours after the end of immobilization exposure, the mRNA concentrations of all three adrenomedullary enzymes returned to control values (in the sympathetic ganglia, in contrast, the highest concentrations were detected during this time interval). Thus, the lowest concentration of TH mRNA in the adrenal medulla and sympathetic ganglia supports the hypothesis that TH is the rate-limiting step in the biosynthesis of CAs.

Effects of Repeated Immobilization Stress on Adrenal Catecholamine-Synthesizing Enzymes

The adrenal response to repeated immobilization stress is summarized in Table 4. Compared to unstressed control rats, rats exposed to immobilization stress for 2 h per day for 6 consecutive days had significant elevations in adrenal medullary mRNA levels of TH, DBH, and PNMT even 24 h after the last stress exposure. In addition, TH, DBH, and PNMT enzyme activities and protein levels were already increased significantly, and each of these changes persisted for at least 24 h. A similar pattern of results was obtained following as few as two consecutive daily bouts of immobilization stress. However, repeated immobilization does not produce further increases in mRNA concentrations compared to the elevated values found in the adapted control group (measured 24 h after six daily immobilization periods). The levels of enzyme immunoproteins both in the adrenal medulla and sympathetic ganglia were significantly increased only after repeated immobilization.

These findings reveal that the adrenal medulla exhibits a transient increase in TH, DBH, and PNMT transcriptional activities following a single 2-h period of immobilization stress. However, these increases in transcriptional activities are not accompanied by increases in enzyme proteins and activities. If animals are exposed daily to immobilization stress for 2–6 days, increases in TH, DBH, and PNMT transcriptional activities, as well as levels of enzyme protein and activity, are enhanced and these increases are maintained for at least 24 h. Thus, the adrenal medulla of repeatedly stressed animals exhibits a significant and long-lasting enhancement of CA biosynthetic capacity already at the level of gene expression. However, as previously noted, these increases in CA biosynthetic capacity develop as the adrenal medulla habituates to repeated immobilization stress and actually releases significantly less EPI with each repeated daily exposure to stress. The importance of the increase in CA biosynthetic capacity is unmasked when a repeatedly stressed animal is exposed to a novel stressor and EPI release from the adrenal medulla is amplified over and above that of a first-time-stressed control.

Table 4 Adrenal mRNA levels and activities of TH, DBH, and PNMT under basal conditions and immediately following six daily 2-h periods of immobilization stress^a

Enzyme	Baseline	mRNA levels post-IMMO ^b	Enzyme activity post-IMMO ^b
TH	100 ± 25	375 ± 20**	320 ± 25**
DBH	100 ± 15	385 ± 40**	255 ± 25**
PNMT	100 ± 10	330 ± 25**	160 ± 10*

^aValues are means ± SEM. * indicates $P < 0.05$ and ** indicates $P < 0.01$ compared to unstressed controls. DBH, dopamine-β-hydroxylase; IMMO, immobilization stress; PNMT, phenylethanolamine-N-methyltransferase; TH, tyrosine hydroxylase.

^bExpressed as percentage of unstressed controls.

The pattern of transcriptional activation and translational control of CA-synthesizing enzymes differs in other models of stress. For example, in animals continuously exposed to a cold environment, TH mRNA levels increased by approximately threefold above baseline within 3–6 h after the start of cold exposure and remained elevated throughout. Levels of TH protein peaked after 3 days of continuous cold exposure and TH activity peaked after 6–7 days of continuous cold exposure. Other stressors such as insulin-induced hypoglycemia, administration of 2-deoxyglucose, and hypoxia have also been shown to affect increases in mRNA, protein levels, and activity of these enzymes in the adrenal medulla. Even social hierarchy affects the gene expression of these enzymes in rats. Gene expression and protein levels were higher in subordinate than in dominant rats.

Finally, it is important to note that stress-induced increases in CA biosynthetic enzymes also occur in tissues other than the adrenal medulla. For example, such changes have been described in various sympathetic ganglia, the heart (PNMT only), several hypothalamic nuclei, and noradrenergic cell bodies of the nucleus locus ceruleus and other brain-stem nuclei.

Factors Influencing Gene Transcription in the Adrenal Medulla during Stress

The Splanchnic Nerve

The chromaffin cells of the adrenal medulla are innervated by terminals arising from the splanchnic nerve. It has been hypothesized that splanchnic input is critical for the enhanced transcription of genes for TH, DBH, PNMT, and various neuropeptides during stressful stimulation. Kvetnansky, Sabban, and their colleagues tested this hypothesis by examining the effects of adrenal denervation on the transcriptional activation of TH, PNMT, and NPY by various stressors.

In their first experiment, the right adrenal gland was intact and the left adrenal gland was denervated in a group of laboratory rats. These animals were then immobilized for 2 h and were sacrificed 3 h later. The results indicated that the immobilization-induced increases in mRNAs for PNMT and TH were not dependent on an intact splanchnic nerve. In contrast, splanchnectomy abolished the stress-induced increase in NPY mRNA (Table 5). In other experiments, it has been shown that an intact splanchnic nerve is required for the increase in enzyme activities for TH and PNMT following immobilization stress. Taken together, these results demonstrate that the splanchnic nerve does play a critical role in the immobilization-stress-induced increase in NPY mRNA and in the increase in TH and PNMT enzyme activities. However, other as yet unidentified factors are responsible for the immobilization-stress-induced increases

in TH mRNA. It should be noted that glucocorticoids are an important regulator of PNMT gene expression.

In another set of experiments, Kvetnansky, Sabban, and their coworkers examined the role of splanchnic input on increases in TH mRNA following three different stressors: cold exposure, insulin-induced hypoglycemia, and immobilization (Table 6). With chronic cold exposure and with insulin-induced hypoglycemia, TH mRNA increased several-fold above basal levels in the intact adrenal, but this increase was completely abolished in the denervated adrenal. In contrast, with immobilization stress there was a significant increase in TH mRNA levels in both the intact and the denervated adrenals. Additional

Table 5 Influence of the splanchnic nerve on transcriptional activation of TH, PNMT, and NPY under basal conditions and 3 h following one 2-h period of immobilization stress

^dSingle 2-h period of immobilization stress with sacrifice 3 h later.

experiments demonstrated that the immobilization-induced increase in adrenal medullary TH mRNA levels is also not dependent on the pituitary gland. The administration of adrenocorticotrophic hormone (ACTH) elicited the induction of TH and DBH gene expression in the rat sympathetic ganglia but not in the adrenal medulla. The ganglia (not the adrenal medulla) were found to express mRNA for melanocortin (MC-2) receptors, which increased after immobilization. Thus, ACTH via the MC-2 receptors may be directly involved in the stress-elicited regulation of NE biosynthesis in the sympathetic ganglia but not in the adrenal medulla. The factors that regulate the increase in TH mRNA in the adrenal medulla of immobilized animals are as yet unknown.

Modulation of Transcription

The expression of genes that encode CA biosynthetic enzymes in the adrenal medulla is mediated by transcriptional mechanisms. The persistence of transcription depends on the duration and repetition of stress stimuli. Recent work identified various transcription factors that are associated with brief or intermediate duration of a single or repeated stressors.

A detailed discussion of the transcription factors and promoters involved in stress-induced increases in mRNAs for TH, DBH, PNMT, and various neuropeptides is beyond the scope of this article. However, it has been shown that the genes coding for the CA biosynthetic enzymes contain several regulatory genomic elements in their promoters. These include the CRE, GRE, API, AP2, POU/Oct, and SP1 sites. The signaling molecules that may influence the transcription rates of the genes for TH, DBH, and PNMT include P-cAMP response element binding protein (-CREB), c-Jun N-terminal kinase (JNK), c-fos, Egr-1, Fra-1, Fra-2, and others. These and other promoters and signaling molecules interact in a complex fashion to regulate mRNA levels for the various adrenal medullary biosynthetic enzymes and neuropeptides under basal conditions and during exposure to stress. The involvement of transcription factors in regulation of gene expression of CA biosynthetic enzymes during stress is not clear yet. However, the present status in the adrenal medulla is as follows. A single episode of stress response-triggered the elevation of c-fos and Fra-2, activation of the mitogen-activated protein kinase (MAPK) JNK, and induction of AP-1 factors, Egr-1, and phosphorylation of CREB. With repeated daily stress exposure, Fra-2 was a major AP-1 factor induced in the adrenal medulla but Egr-1 levels were also markedly elevated. For PNMT gene expression, two transcription factors are especially important: glucocorticoid receptor and Egr-1. The crucial role of glucocorticoids in PNMT gene regulation has

also been confirmed in corticotropin releasing hormone (CRH) knockout mice.

Thus, different transcription pathways are involved in the mediation of the elevated gene expression of CA biosynthetic enzymes during acute or chronic/repeated stress. Recently, the genetic determinants of the sympathoadrenal response to stress have been mapped.

Summary and Conclusion

The adrenal medulla and the concept of stress are inextricably intertwined. The adrenal medulla may function in concert with the sympathetic nervous system, or it may function somewhat independently in meeting the homeostatic demands presented by a variety of stressful stimuli. Although EPI secretion has been the primary focus of physiological studies of the adrenal medulla, it is now apparent that the adrenal medulla secretes a complex array of neuropeptides that exerts effects in the adrenal medulla and throughout the body. The adrenal medulla is innervated by preganglionic sympathetic nerve terminals that release acetylcholine and various colocalized peptides.

A major focus of studies beginning in the early 1970s concerned the ways in which the adrenal medulla responds to acute versus repeated exposure to stress. With the advent of sensitive and specific assay techniques, it has been shown that a complex cascade of biosynthetic changes occurs within the adrenal medulla as animals adapt to stressful stimuli.

Finally, an important lesson that has been learned relates to the stressor-specific pattern of molecular responses of the adrenal medulla. Although many stressors result in increases in mRNA levels for TH and other biosynthetic enzymes, these changes may be dependent on an intact splanchnic nerve or on an as yet unidentified mechanism that is independent of the splanchnic nerve.

In spite of thousands of experiments on the adrenal medulla and stress, there are many important questions that await answers. What mechanism explains the reduced secretion of EPI from the adrenal medulla of animals exposed to chronic intermittent stress and the enhanced secretion of EPI following the exposure of chronically stressed animals to a novel stressor? What factors regulate the increased levels of mRNAs for TH, DBH, and PNMT in the adrenal medulla versus other organs following exposure to various stressors? What are the roles played by the various neuropeptides that are released from splanchnic nerve terminals and from adrenal medullary chromaffin cells, and how do these substances interact with EPI? What is the exact mechanism of the transcription process and involvement of transcription factors

during a single and chronic stress exposure? These and other questions are being addressed by many research groups throughout the world. As answers become available, our knowledge of the physiological and molecular aspects of stress will be enhanced.

The Effects of Adrenaline

Measuring Adrenaline Levels

Psychosocial Determinants of Adrenaline Variation

Individual Differences in SAM Reactivity

Conclusion

Glossary

<i>Adrenal glands</i>	Endocrine glands situated above the kidneys, composed of two distinct parts, the adrenal medulla, which secretes adrenaline and noradrenaline, and the adrenal cortex, which secretes corticosteroids.
<i>Adrenergic receptors</i>	Receptors that mediate the action of adrenaline. There are two types, α and β receptors.
<i>Atherogenic</i>	Encouraging the process of atherosclerosis, which is a change in the lining of arteries consisting of an accumulation of lipids, complex carbohydrates, blood and blood products, fibrous tissue, and calcium deposits.
<i>Catecholamine</i>	A group of hormones, including adrenaline, norepinephrine (noradrenaline), and dopamine, which are synthesized from the amino acid tyrosine.
<i>Job strain</i>	A construct used to describe work that makes heavy demands but offers little decision latitude for the worker.
<i>Sympathetic tone</i>	The basal rate of activity of the sympathetic nervous system.

Adrenaline, also known as epinephrine, is the main catecholamine produced by the adrenal medulla. Its secretion into the adrenal vein is under the control of

sympathetic nerves and is the most important indirect pathway of sympathetic activation. Adrenaline plays a major role in the body's physiological response to stress and affects most systems of the body. The axis as a whole is referred to here as the sympathetic adrenal medullary (SAM) axis.

The Effects of Adrenaline

The effects of adrenaline are similar to those of direct sympathetic stimulation, but they last considerably longer. Once in the bloodstream, adrenaline stimulates α and β adrenergic receptors. Through stimulation of cardiac muscle β receptors it causes an increased heart rate, force of contraction, and cardiac output. Its actions on vascular smooth muscle adrenergic receptors cause the shunting of blood away from the skin, mucosa, and kidneys to the coronary arteries, skeletal muscle, and brain. Adrenaline also enhances blood platelet adhesiveness and reduces clotting time. It promotes the role of glucagon in converting glycogen to glucose, leading to an increased secretion of glucose into the bloodstream and production of glucose in the liver. Experimental studies have shown a highly significant increase in glucose levels during infusion of adrenaline. In addition, lipolytic activity in adipose tissues is stimulated, with a resultant increase in levels of plasma free fatty acids, providing another source of energy. There is also an increase in plasma cholesterol levels, including both low-density and high-density fractions, but this effect may be at least partially explained by a reduction in plasma volume. Oxygen supply is improved, as a function of both vascular changes and bronchodilation. As a result, the body is prepared for immediate physical and mental activity, and the response is often referred to as the fight or flight reaction. This emergency function of the adrenal medulla was first identified by Cannon in 1914. At least over a few hours of secretion there appears to be no regulatory mechanism to counteract the effects of adrenaline; that is, these effects are sustained for as long as secretion of the hormone is maintained.

It is thought that repeated adrenaline secretion, or chronically raised levels of adrenaline, are likely to increase risk of cardiovascular disease, partly by changing sympathetic tone and partly by inducing changes that accelerate the process of atherosclerosis. Infusion of adrenaline leads to a sustained rise in blood pressure, and repeated elevation of blood pressure may eventually lead to hypertension via enhanced sympathetic tone and damage to the blood vessels. It is likely that chronic elevation of adrenaline levels may lead to long-term elevation of lipid levels. The free fatty acids whose release is stimulated by adrenaline are used by the liver for the synthesis of very low density lipoproteins, which then become modified to low-density lipoproteins, which are strongly implicated in the atherogenic process. Adrenaline may have a direct role to play in myocardial infarction or cerebrovascular accident through its effects on platelets and clotting time and by the precipitation of cardiac arrhythmias.

Adrenaline can alter a number of aspects of immune function and may well mediate some of the apparent effects of stress on susceptibility to infectious disease and cancers. Studies show that individuals who show large increases in adrenaline in response to laboratory stressors also show the largest immune changes. Furthermore, adrenergic blockers have been demonstrated to prevent stress-induced increases in natural killer cell number and activity. Adrenaline is thought to act on the immune system by altering lymphocyte migration from lymphoid organs such as the spleen.

Measuring Adrenaline Levels

It is possible to determine adrenaline levels in plasma or urine. The main methods used are high-performance liquid chromatography and radioenzymatic assay. The former uses high pressure to separate catecholamines, and this is usually followed by electrochemical detection. The latter relies on radioactive labeling – a radioactive substrate is added together with an enzyme, and the amount of radioactive metabolite formed is measured. Both techniques have been validated and are known to be reliable, but neither is cheap.

Levels of hormone in plasma and urine reflect neuroendocrine activity over different time periods, and it is important to use the appropriate medium. The SAM axis responds to stimuli within a few seconds of their impact, and plasma adrenaline has a half-life of 1 to 2 min, so that levels of hormone in plasma reflect the SAM activity of only the preceding minute or so. Thus, assessment of plasma adrenaline levels is only generally useful for laboratory studies of acute stressors, when an indwelling venous catheter can be used (since venipuncture itself is known to cause an

increase in adrenaline levels). Samples must be spun and frozen very shortly after collection.

Levels of excreted free adrenaline or its metabolites can be measured in urine and have been shown to provide an accurate measure of circulating levels. Hormone assayed in urine usually represents a pooling of levels over a period of hours. This is partly because hormone measured in urine is an integration of the hormone excreted into the urine produced by the body since the previous urination, and partly because excreted hormone reflects hormone secreted some time before. Information on the time lag between secretion and excretion is sparse, although some laboratory studies have produced results indicating that urinary adrenaline excretion rate reflects plasma adrenaline levels within an hour. When samples are collected over a few hours, it is important to make some correction for variation in the amount of urine produced during that time. It is also possible to collect all the urine produced in a given 24-h period in order to look at the overall level produced during a day. However, it is not always easy for study participants to comply with the demands of 24-h collection, and some checking for completeness of the sample is often needed, by assessing either total volume or creatinine clearance. Again, degradation and oxidation is a problem, and an antioxidant such as sodium metabisulphite is usually added to urine samples collected for the purpose of catecholamine determination.

Psychosocial Determinants of Adrenaline Variation

Researchers interested in understanding psychosocial determinants of adrenaline variation have investigated changes in hormone levels within individuals as well as differences between individuals. In general, the former approach has been more successful. As we have seen, adrenaline levels respond quickly to changing circumstances, and a lot of information can be gained from examination of changes in hormone levels over time. Comparisons between individuals usually focus on longer-term measures, such as 24-h urinary excretion rates, and thus only make use of averaged information for each subject. Data on within-individual variability is lost, and it is known that adrenaline excretion rates vary as much or more within individuals as they do between them. Furthermore, absolute levels of hormone are influenced by a large number of factors other than stress or the psychosocial environment, so that it is much more useful if each person can be used as his or her own control.

The main findings of studies examining the reasons for variation in adrenaline levels are summarized

below, looking first at laboratory studies and then at those that have been conducted in people going about their normal lives.

Laboratory Studies of the Determinants of Adrenaline Secretion

The largest body of research on adrenaline responses in humans has been undertaken in laboratories. In general, the focus of these studies has been measuring the adrenaline response to situations and stimuli that are assumed to be stressful. Mason reviewed the early work in an important article published in 1968. He described situations in which adrenaline levels had been shown to rise in humans. These included watching engaging movies, taking examinations, and performing set tasks such as intelligence tests or mental arithmetic. He concluded from these findings that adrenaline can rise in emotionally arousing situations that are pleasant as well as in those that are unpleasant. Since the 1960s, other workers have reported results that can be interpreted in the same way. As a result of these findings, Frankenhaeuser put forward a model in which the SAM axis was considered to be activated in response to mental or physical effort, regardless of emotional content. These studies provided some indication that adrenaline responses in women are less marked than those in men.

Adrenaline Variation in Everyday Life

Influences of habitual health-related behaviors Adrenaline levels respond to a number of features of human behavior, not just the experience of psychosocial stress. Those that have received the most attention and that are probably most important are the intake of caffeine, nicotine, and alcohol and taking exercise. All have been shown to stimulate adrenaline secretion. Caffeine also appears to potentiate adrenaline responses to stress. In laboratory studies it is possible either to eliminate these influences or to control them. Researchers hoping to isolate the effects of psychosocial stressors outside the controlled laboratory environment have a more difficult task. They have sometimes approached the problem by asking subjects to avoid these influences. However, such an approach can bring problems of its own, perhaps, for example, inducing stress in smokers asked to abstain from cigarettes. Thus, others have asked subjects to keep detailed records of their behavior and included this information in subsequent analyses.

Adrenaline variation across societies Biological anthropologists have examined cross-cultural variation

in adrenaline levels and have tried to relate the observed variation to differences in lifestyle. Such cross-sectional data suffer from the problems described previously, but some of the findings are nevertheless suggestive. In general, people living in more urbanized environments appear to excrete higher levels of urinary adrenaline than those engaged in traditional subsistence farming work, despite the lower levels of physical activity characteristic of urbanites. For example, James and colleagues compared urinary adrenaline excretion rates in young Western Samoan men living in villages or the capital, and showed that men living in the city, whether nonmanual workers, students, or laborers, excreted higher levels of urinary adrenaline than villagers on average. Similarly, Tokelauans living on Fakaofu had higher levels of urinary adrenaline than residents of Nukunonu, a nearby island less influenced by the wage economy. Still higher levels were excreted by Tokelauan migrants to New Zealand living in the urban center of Wellington. In both these studies the results were explained largely with respect to working behavior, with the suggestion that engagement in paid work, as opposed to traditional subsistence work, was more stressful.

Adrenaline variation in everyday working life In addition to their laboratory work, Frankenhaeuser and her team also pioneered investigations of the ways in which work-related stress might affect adrenaline levels. Two main kinds of comparisons have been made. The first contrasts hormone levels in people at work and at leisure, usually using a within-subject design; the second compares the effects of different types of work on hormone variation. The comparison of work and leisure addresses the question of whether nonmanual work *per se* causes an increase in adrenaline secretion. It is then relevant to ask what particular aspects of work are associated with elevated adrenaline levels.

There is good evidence that adrenaline levels are higher in men at work than in the same men at leisure. In a particularly large study, researchers in Oxford also found that in a diverse sample of British men, who provided urine samples on a normal working day and on Sunday, a rest day, urinary adrenaline levels were higher on the working day. Women who gave samples as part of the same study also showed significantly raised adrenaline levels on work days. However, there is some suggestion that the effect is not as consistent in women. In another study conducted in the same area, it was found that while men's urinary adrenaline levels were raised on working days, those for women were not, despite the fact that men and women reported experiencing very similar levels of demand.

Taken together, the results of a series of studies can be interpreted to show that workload and time pressure are the key features leading to elevated adrenaline levels at work. For example, increased urinary adrenaline levels in Swedish bus drivers when traffic was heavier were attributed to greater perceived time pressure created by the demands of remaining on schedule. Elevated adrenaline levels have also been seen in sawmill workers operating under time pressure and in people working on conveyor belts.

Efforts have been made to relate variation in adrenaline levels at work to the model of job strain proposed by Karasek and widely tested and applied in studies of workplace stress. Karasek and Theorell suggested that endocrine mechanisms explain the apparent link between job strain and ill health, particularly cardiovascular disease. They proposed that adrenaline is secreted at higher levels in those experiencing job strain due to a heavy workload and lack of decision latitude. However, Karasek acknowledged that adrenaline can also rise with increased workload, whether decision latitude is high or low. There is, then, a general consensus that adrenaline levels are most strongly related to arousal or effort, as in Frankenhaeuser's original model.

Individual Differences in SAM Reactivity

Not all people show the same SAM responsivity to stressors. It has been proposed that more reactive individuals are at greater risk of cardiovascular disease.

Sex Differences

Most early studies of the effects of stress on adrenaline in humans were conducted with only male participants. When researchers began to include women, they found that their responses to stressors were not always the same as men's, as noted previously. It is possible that the high circulating levels of estrogen seen in premenopausal women modify the way in which adrenaline is secreted in response to stress. Evidence for such an effect comes from comparisons of post- and premenopausal women and from studies of women given exogenous estrogen, as, for example, in hormone replacement therapy for postmenopausal women. There is little evidence to support an alternative explanation for increased adrenaline responses in men – that they find exposure to stressors more stressful.

Age

Little is known about the reactivity of the SAM system in normal children. There is evidence that in adults adrenaline secretion in response to acute

laboratory stressors declines with age, for example, in 60- to 75-year-old men compared to 20- to 30-year-old men. It is also the case that basal adrenaline secretion from the adrenal medulla declines with age in adults, but because plasma clearance is reduced too, plasma adrenaline concentrations do not decline.

Individuals Experiencing Chronic Stress

In contrast to initial suggestions, recent findings indicate that those experiencing chronic stress (at work, in relationships, or as caregivers) do not show greater adrenaline reactivity to acute laboratory stressors compared to those not experiencing such chronic stressors.

Conclusion

Adrenaline has widespread and important effects on the body, and these effects have clear-cut implications for cardiovascular disease. It is the hormone most consistently shown to respond to stress both in laboratory studies and in people going about their everyday lives. However, adrenaline also responds to experiences not usually considered stressful, since it rises with mental arousal or effort, whether of a negative or a positive connotation. Furthermore, the adrenaline response may not be consistent across all individuals or all stages of the life course.

Development of the Adrenal Cortex: From the Urogenital Ridge to the Definitive Adrenal Gland
Transcription Factors Involved in Adrenocortical Development
Transcriptional Establishment of Adult Adrenocortical Function

Glossary

Adrenal steroidogenesis Process by which steroid hormones are synthesized from the cholesterol precursor. This multistep process involves several enzymes that together form the adrenal steroidogenic pathways of mineralocorticoid (aldosterone), glucocorticoid (cortisol) and androgen (dehydroepiandrosterone [DHEA]) synthesis.

Adrenocortical primordium Structure within the craniomedial part of the urogenital ridge that harbors the precursor cells for the adrenal cortices. Arises from the adrenogonadal primordium.

Genetically engineered animals Knockout animals are engineered for loss of a gene. Transgenic animals harbor genetically engineered multiple copies of one gene in their genome. Tissue-specific

knockout/transgenic animals are engineered animals that display loss or transgenic gain of a gene in a tissue-specific manner.

Hypothalamus-pituitary-adrenal (HPA) axis

Endocrine stress axis. Higher brain centers control hypothalamic CRH (corticotropin-releasing hormone) release, which in turn leads to the release of ACTH (adrenocorticotropin) from the pituitary corticotroph cells. ACTH stimulates cortisol synthesis and release in the adrenal gland.

Nuclear hormone receptor (NHR)

Family of transcription factors, usually activated by hormone/ligand binding (e.g., estrogen receptor, glucocorticoid receptor). Further members of the NHR family referred to as orphan NHRs, for which a ligand is unknown to date, have been discovered through homology screening.

POMC, ACTH

ACTH is the main tropic pituitary hormone for stimulating adrenal glucocorticoid release. It is derived from a peptide precursor, proopiomelanocortin (POMC), which also gives rise to several other peptides with diverse function, e.g., N-POMC (N-terminal POMC fragment) stimulating adrenocortical cell growth and MSH (melanocyte-stimulating hormone) stimulating skin pigmentation and regulating satiety circuits.

<i>Renin-angiotensin-aldosterone (RAA) system</i>	System to regulate body sodium homeostasis and blood pressure. Aldosterone release from the zona glomerulosa cells is regulated by angiotensin II and potassium. Angiotensin II is generated by conversion of angiotensinogen to angiotensin I by renin and subsequent conversion of angiotensin I to angiotensin II by angiotensin-converting enzyme.
<i>Transcription factor</i>	Protein factor that influences ([trans] represses or [trans]activates) gene expression through binding to certain response elements within the DNA of a gene promoter or enhancer. Transcription factors can interact with each other and mutually modify their ability to activate or repress gene transcription.
<i>Urogenital ridge</i>	Embryonic precursor that is visible as a ridgelike structure on both sides of the dorsal developing body cavity (coelom). The urogenital ridge gives rise to the adrenal cortex, the gonad (testis or ovary), and the kidney.

To serve as the functional end organ of the hypothalamus-pituitary-adrenal (HPA) axis and the renin-angiotensin-aldosterone (RAA) system, the adrenal gland needs to develop into an organ that is capable of responding to specific extrinsic stimuli with the release of different steroid hormones. While the ortholog of the adrenal cortex in lower species, the interrenal organ, consists of intermingled steroidogenic cells within the renal organ, the mammalian adrenal gland is organized into a distinct organ, which is morphologically and functionally zoned. The definitive adult human adrenal cortex comprises three functional zones: the outermost mineralocorticoid-producing zona glomerulosa, the glucocorticoid-secreting zona fasciculata, and the inner zona reticularis, which mainly secretes adrenal androgens.

The regulation of the embryonic development of the adrenal cortex can be divided into three consecutive steps. The first of these is a spatially and temporally regulated program of expression of developmental factors, mainly transcription factors, which induce differentiation and morphological shaping of the adrenogonadal primordium and the later adrenocortical primordium within the urogenital ridge. Second, during late pregnancy functional differentiation becomes increasingly controlled by endocrine factors, secreted by the pituitary (adrenocorticotropin [ACTH] and other proopiomelanocortin [POMC] peptides). The importance of this step is evident in autopsy findings from anencephalic fetuses, in which the adrenal cortex is usually hypoplastic and lacks a sufficient functional zonation.

Last, in adult life the adrenal cortex is a dynamic organ, undergoing a constant cell renewal. Steroid output and tissue growth are regulated dynamically to fit the homeostatic needs of the organism.

Development of the Adrenal Cortex: From the Urogenital Ridge to the Definitive Adrenal Gland

The adrenal gland is of mesodermal origin and is a derivative of the urogenital ridge. The ridgelike impression of this precursor organ becomes evident on both sides of the coelomic cavity in the second month of human embryonic development and is mainly formed by the developing mesonephros. Though the actual origin of the earliest adrenal precursor cells is still enigmatic, with recent observations suggesting a contribution of the intermediate mesoderm, classical studies describe a proliferation and condensation of coelomic epithelial cells lining the mesonephros as the earliest event of adrenocortogenesis. The adrenogonadal primordium can be visualized within the urogenital ridge by positive staining for the common marker steroidogenic factor-1 (SF1). This common structure further gives rise to the adrenocortical and gonadal primordium. At approximately 8 weeks, two different zones can be distinguished in the adrenocortical primordium, the outer definitive and the inner fetal zone. It is not yet established whether this morphological change is caused by a differentiation event of preexisting cells or a distinct migratory event of precursor cells. By the end of the ninth week, the developing adrenal gland becomes encapsulated, and migrating cells of neural crest origin form the precursor cells of the adrenal medulla. The clear demarcation of the two organ structures, cortex and medulla, becomes evident around term, when most of the fetal zone cells undergo apoptosis. Therefore, at birth the human adrenal cortex consists of the derivatives of the definitive zone (zona glomerulosa and zona fasciculata) and a regressing fetal zone. Later in life, at the time of adrenarche, a third zone appears between the zona fasciculata and adrenal medulla, the androgen producing zona reticularis. This zone is unique to primate species.

Notably, defects occurring at particular stages of adrenocortical development can additionally manifest in defective development of other urogenital ridge derived organs, namely, the gonad or kidney.

Transcription Factors Involved in Adrenocortical Development

There is emerging evidence of a myriad of signaling pathways and transcription factors involved in

adrenocortical development. As a result of the elucidation of the molecular basis of the genetic disorder cytomegalic adrenal hypoplasia congenita (AHC) and the investigation of several mouse models of disturbed adrenal development, it has become clear that the two orphan nuclear hormone receptors (NHRs), DAX1 (dosage-sensitive sex reversal-adrenal hypoplasia region on the X chromosome) and SF1, can be considered to comprise a central signaling network of adrenal development and differentiation. On the molecular level, there are several functional interactions between these factors that mutually influence their potential for transcriptional regulation as well as their own expression levels.

Steroidogenic Factor-1

SF1 belongs to the NHR superfamily and shares an overall domain homology with other members of this transcription factor family. SF1 harbors a classical zinc finger domain, which enables it to bind to its cognate response element in the promoter of SF1-regulated genes. The two activation function domains (AF-1, AF-2) of SF1 direct interaction with other transcription factors (e.g., WT1, SRY-related HMG box gene 9 [SOX9], GATA-binding protein 4 [GATA-4]), coactivators (e.g., CREB-binding protein [CBP/p300], steroid receptor coactivator 1), and corepressors (e.g., nuclear receptor corepressor [NCoR]). These interactions are dependent on posttranslational modifications such as phosphorylation, through the mitogen-activated protein kinase (MAP kinase) signaling pathway, and sumoylation. In the case of steroidogenic genes, SF1 has been shown to enhance transcription via the cAMP/PKA (cyclic adenosine monophosphate/protein kinase A) and the MAP kinase pathway. The molecular bases of these mechanisms are not well understood.

The recent description of the crystal structure of Sf1 revealed phospholipids in the pocket of the ligand-binding domain. Future experiments need to determine whether binding of these lipid moieties serves as a regulatory mechanism or as a constitutional part of the SF1 complex.

SF1 is a critical determinant of adrenocortical growth and differentiation. SF1 is the earliest marker of the adrenogonadal primordium in the urogenital ridge and is an essential factor for expression of several steroidogenic genes. Mice deficient in Sf1 die perinatally due to adrenal insufficiency and exhibit complete absence of adrenal glands and gonads, loss of pituitary gonadotropes, and absence of the ventromedial hypothalamus. Increased apoptosis can be detected within the adrenal primordium and the genital ridge of *Sf1*^{-/-} mice, outlining the role of SF1 and

SF1-induced genes as crucial survival factors for the adrenogonadal primordium.

The importance of Sf1 in murine adrenocortical growth and development has been further underscored by the finding that *Sf1* haploinsufficient mice have a decreased cell number in the adrenal primordium and adult adrenal gland, while the degree of steroidogenic potential per cell is elevated.

Recently, several human patients with mutations in *SF1* have been described. Partially resembling the *Sf1* knockout model, and in accordance with a crucial role of *SF1* in adrenogonadal primordium differentiation, these patients display varying degrees of XY sex reversal and adrenal insufficiency, confirming the essential role of SF1 in growth regulation of the adrenal cortex.

DAX1

DAX1 was initially cloned as the gene responsible for the most common variant of congenital AHC, cytomegalic AHC. Male XY patients with *DAX1* mutations present with hypogonadotropic hypogonadism and adrenal insufficiency. AHC is defined as a hypofunctional adrenal gland composed of a retained cytomegalic (non-regressed) fetal zone and dysfunctional definitive zone. In the adrenogonadal primordium, *Dax1* is detectable shortly after *Sf1*, which induces *DAX1* expression through binding to the *DAX* promoter.

Like SF1, DAX1 belongs to the family of NHR, but represents a rather atypical member of this family, as it contains the conserved ligand-binding domain but lacks the typical zinc finger DNA-binding motif. DAX1 contains three copies of a novel 67- to 69-amino-acid repeat that alternately has been reported to bind DNA or polyadenylated RNA and can therefore regulate gene expression on the transcriptional as well as translational level. DAX1 negatively regulates SF1-mediated gene expression via two main mechanisms. First, DAX1 can directly bind SF1 through one of its N-terminal LXXLL motifs; second, it binds to particular DNA structures in the promoter regions of certain genes, e.g., steroid acute regulatory protein gene (*Star*). Interaction with the corepressor Alien and NCoR may be partly responsible for DAX1-mediated gene repression.

DAX1 function provides a feedback mechanism for SF1-mediated transcription, because SF1 induces its own repressor (DAX1) and successively inhibits SF1 function. Though there is a significant overlap of *DAX1* and *SF1* expression, not all *DAX1*-expressing cells stain positive for SF1, giving evidence for functions independent of repression of SF1-mediated transactivation. Indeed, DAX1 has been shown to

repress the function of several other ligand-activated NHR.

Additional complexity arises from the description of a novel *DAX1* splice variant in human tissue. As a result of splicing to two alternative exons, the *DAX1* gene gives rise to two isoforms: *DAX1* and *DAX1A*. Though *DAX1A* does not show a high degree of phylogenetic conservancy and its physiological significance has yet to be proven, the occurrence of a C-terminal truncated *DAX1* is of special interest, because this isoform has been shown to transcriptionally synergize with SF1 in contrast to the mutual inhibitory effect of the classical *DAX1* and SF1.

Other Factors

Several other signaling pathways and transcription factors have been implicated in adrenocortical development. Most of our knowledge about these factors is derived from genetically engineered mouse models and rare human disorders. Depending on the temporal expression of a given transcription factor during adrenocortical development from the urogenital ridge, the formation of additional organs can be compromised. For example, disruption of *Wt1* (Wilms tumor 1) results in a renal and gonadal phenotype, and, on certain mouse strain backgrounds, the absence of the adrenal gland is evident.

Other common developmental pathways, such as the Wnt- or hedgehog-signaling networks, are involved in adrenocortical development as well. Disturbed hedgehog signaling, as in Pallister–Hall syndrome, causes not only skeletal deformation but also a varying degree of adrenal hypoplasia or complete absence of the organ, demonstrating the pleiotropy of these signaling pathways. The Wnt-signaling pathway is of special interest, as its downstream activated transcription factor β -catenin and SF1 can act synergistically to activate gene transcription.

Recent descriptions of knockout mouse models for the transcription factor *Pbx* and the transcriptional cofactor *Cited2* added two animal models displaying absence of the adrenal gland.

Future tissue-specific (adrenal-specific, e.g., *Sf1-Cre*-driven) knockouts of developmental factors will help clarify the complex transcriptional control of adrenocortical development.

Transcriptional Establishment of Adult Adrenocortical Function

The establishment of a fully functional adult organ requires the regulated expression of the various steroidogenic enzymes that generate steroid hormones

from the precursor, cholesterol. This is achieved by the activation of tissue-specific transcription factors, e.g., SF1, that orchestrate the activation of steroidogenesis in response to the stress-induced release of tropic hormones, e.g., ACTH or angiotensin. While acute ACTH-mediated steroid output is not dependent on acute transcriptional activation (transcriptional effects occur within hours, while cortisol release occurs within minutes), ACTH signaling induces steroidogenic gene transcription to ensure sufficient steroidogenic potential and ultimate steroid secretion. Expression levels of critical steroidogenic enzymes match the functional needs of the endocrine response. The main ACTH-signaling pathway is the cAMP/PKA pathway, but others have also been shown to be important (e.g., mitogen-activated protein kinase pathways). The transcriptional regulation of steroidogenic genes is outlined with two examples: *StAR*, which encodes a non-zonal-specific mitochondrial cholesterol transporter, and the zone-specific genes encoding CYP11B1, which converts deoxycortisol to cortisol and is predominantly expressed in the zona fasciculata, and CYP11B2, which is specifically expressed in the zona glomerulosa and catalyzes the last step in aldosterone synthesis.

StAR

StAR-mediated cholesterol transport is a rate-limiting event in steroidogenesis and is in great part regulated posttranslationally, e.g., direct protein phosphorylation by PKA. In addition, the transcriptional regulation of *StAR* is an example of tissue-specific as well as dynamically regulated (stress-induced and endocrine-mediated, e.g., ACTH stimulation) gene expression. Tissue specificity is achieved by transcriptional regulation through SF1 and DAX1. In the human promoter, two binding sites for SF1 regulate basal expression of *StAR*. Through the mutual antagonism of DAX1 and SF1, *StAR* expression can be downregulated directly by DAX1 interference of SF1-mediated transactivation of the *StAR* promoter. Furthermore, DAX1 has been shown to directly bind to a hairpin loop and repress transcription independent of SF1. Other basal transcription factors, which in part may play a role in tissue specificity as well as regulating basal transcription, are SP1 and GATA4. Most of the acute induction of human *StAR* promoter activity is provided by SF1, underlining the importance of SF1 not only for tissue specificity, but also for regulated transactivation upon stimulation with tropic hormones/cAMP. For the mouse *StAR* promoter, interaction of phosphorylated CREB (cAMP-responsive element binding protein), the classical downstream transcription factor of the cAMP/PKA

pathway, with a DNA element in the StAR promoter has also been recently reported.

CYP11B1 and CYP11B2

These two enzymes differ considerably in their intra-adrenal expression patterns, in accordance with their functions. *CYP11B1*, an enzyme mainly of the cortisol synthesis pathway, is expressed in the glucocorticoid-secreting zona fasciculata and is, like the *StAR* gene, regulated by SF1. *CYP11B2*, however, as the final enzyme in aldosterone synthesis, is expressed in the mineralocorticoid-secreting zona glomerulosa. Therefore, transcription of this gene needs to be regulated in a zone-specific pattern and needs to respond to angiotensin II and potassium as the main stimuli for mineralocorticoid production. Recently, nerve growth factor-induced clone B (NGFIB) and Nur-related factor 1 (NURR1) have been shown to selectively induce *CYP11B2* transcription. *NURR1* has further been shown to be expressed upon angiotensin and potassium stimulation. Moreover, the expression level of *NURR1* is highest in the zona glomerulosa and decreases in a centripetal pattern. Therefore, *NURR1* is an illustrative example of a distinct spatial- and stimuli-dependent transcription factor specific for zona glomerulosa function and mineralocorticoid synthesis within the adrenal gland.

Introduction

Control of Secretion

Negative Feedback Mechanisms

Glossary

<i>Adrenal androgens</i>	Hormones produced by the adrenal cortex that have weak male sex hormone-like effects.
<i>Amygdala</i>	Bilateral nerve cell nuclei in the temporal lobes of the forebrain that are concerned primarily with fear processing and which stimulate the secretion of corticotropin-releasing hormone and, in turn, the rest of the hypothalamic-pituitary-adrenocortical axis.
<i>Catecholamine</i>	Any of a group of amines derived from catechol that has important physiological effects as neurotransmitters and hormones. Examples of catecholamines include epinephrine (adrenaline), norepinephrine (noradrenaline), and dopamine.
<i>Circadian rhythms (diurnal rhythms)</i>	A daily rhythmic activity cycle, based on 24-h intervals, that is exhibited in the physiological functions, including hormone secretions, of many organisms.
<i>Glucocorticoids</i>	Hormones produced by the adrenal cortex that increase glucose production in the liver, inhibit glucose metabolism by body tissues, and promote lipid breakdown in fat tissue. The principal glucocorticoid in humans is cortisol (hydrocortisone). When administered in high, therapeutic doses, glucocorticoids suppress immunological function, reduce inflammation, and decrease connective tissue and new bone formation.
<i>Hippocampus</i>	An area of the brain containing nerve cells that inhibit the secretion of corticotropin releasing hormone and, in turn, the rest of the hypothalamic-pituitary-adrenocortical axis.
<i>Hypothalamic-pituitary-adrenocortical (HPA) axis</i>	A hormone axis consisting of cells in the hypothalamus of the brain that secrete corticotropin-releasing hormone (CRH) and vasopressin (AVP), which

Mineralocorticoids

Proopiomelanocortin (POMC)

Vasopressin (AVP)

stimulate the secretion of adrenocorticotrophic hormone (ACTH) from the anterior pituitary gland into the bloodstream. In turn, ACTH stimulates the adrenal cortex to secrete glucocorticoids, mineralocorticoids, and adrenal androgens into the bloodstream.

Hormones produced by the adrenal cortex that reduce the excretion of sodium and enhance the excretion of potassium and hydrogen ions by the kidney. The principal mineralocorticoid in humans is aldosterone.

Precursor polypeptide that is synthesized within anterior and intermediate lobes of the pituitary gland. Products from POMC include adrenocorticotrophic hormone (ACTH) and β -endorphins.

A hormone produced by cells in the hypothalamus that is transported down the pituitary stalk to (1) the anterior pituitary gland, where, along with CRH, it stimulates the secretion of ACTH, and (2) the posterior pituitary gland, where it is carried by the bloodstream to the kidneys, where it reduces the excretion of water. Also known as antidiuretic hormone (ADH).

Introduction

Advances in the measurement of adrenocorticotrophic hormone (ACTH) and its related peptides have elucidated their extensive distribution in the body outside the pituitary gland, with differential processing in different tissues. ACTH and other peptides, including β -endorphin, a peptide known for its analgesic and euphoric effects in the brain, are produced in the pituitary from the enzymatic cleavage (posttranslational processing) of a large precursor protein, proopiomelanocortin (POMC) (Figure 1). POMC is processed in the anterior lobe to yield an N-terminal peptide, whose function is unclear, and the peptides ACTH and β -lipotropin (β -LPH). ACTH and β -LPH are secreted by the anterior pituitary. α -Melanocyte-stimulating hormone (α -MSH) and corticotropin-like intermediate lobe peptide are contained within the ACTH molecule. These peptides are found in species with a distinct intermediate lobe (e.g., amphibians, reptiles, rats); however, they are not secreted as separate hormones in humans. Within the β -LPH molecule exists the amino acid sequence for γ -LPH, β -endorphin, β -MSH, and metenkephalin.

Figure 1 Proopiomelanocortin (POMC) and its biologically active peptide hormones following processing. POMC products are cleaved in a tissue- and species-specific manner. Bioactive products include adrenocorticotrophic hormone (ACTH), lipotropin (LPH), α -melanocyte-stimulating hormone (α -MSH), corticotropin-like intermediate lobe peptide (CLIP), and β -endorphin (β -End).

Evidence from light microscopic studies has suggested that in the anterior pituitary ACTH is secreted by basophilic corticotropes that represent 15–20% of the anterior pituitary cell population. With the electron microscope, ACTH-producing cells appear irregularly shaped and full of secretory granules. The complete structure of ACTH is known and the hormone has been synthesized. The entire molecule is not needed for biological activity. The first 16 amino acids beginning with the N-terminal amino acid are all that is required for minimal biological activity. Progressive increases in activity occur as the length of the chain increases until full biological activity is present with a polypeptide over 22 amino acids long. ACTH, a 39-amino-acid peptide, has a circulating half-life of 7–12 min. The development of immunoradiometric assays specific for intact human ACTH_{1–39} has improved the reliability of ACTH measurement. Radioimmunoassay of plasma ACTH and its precursors also is an accepted method for evaluating ACTH secretion, although the antibodies used also recognize some ACTH fragments. Glucocorticoid concentrations in the blood also can be measured as an index of ACTH secretion.

Control of Secretion

The regulation of ACTH secretion primarily involves the stimulatory effect of corticotropin-releasing hormone (CRH) and vasopressin (AVP), hypothalamic hormones released directly into the portal blood supplying the anterior pituitary, and the inhibitory effect of glucocorticoids. The participation of other regulators in addition to CRH and AVP, modulating ACTH secretion in the absence of or during stress,

Figure 2 Factors influencing the ACTH secretion from the anterior pituitary. Peripheral vasopressin and cortisol feedback directly modulate ACTH secretion, while other factors such as stressors, circadian rhythms, cortisol feedback, and neurotransmitters modulate its release by influencing the portal secretion of CRH and vasopressin from the paraventricular nucleus of the hypothalamus. Dashed lines represent negative feedback or inhibition; solid lines represent stimulation.

can not be discounted (Figure 2). A number of other factors, such as angiotensin II, catecholamines, and immune factors, have been shown to stimulate ACTH secretion.

Areas of the brain, including the amygdala, hippocampus, and hypothalamus, stimulate and inhibit the hypothalamic-pituitary-adrenocortical (HPA) axis to different degrees depending on the time of day, season of the year, and physical and environmental stressors. The HPA axis has a normal circadian (24-h) rhythm: The secretion of CRH, ACTH, and adrenal hormones is greatest between 7 and 8 a.m., an hour or so after awakening, and lowest in early morning between 2 and 3 a.m.

HPA axis function also is intimately linked with immune function. Interleukins are chemical messengers secreted by cells of the immune system that affect the behavior of the rest of the immune system. In addition to their effects on immune function, interleukin-1 (IL-1), IL-2, and IL-6 appear to stimulate HPA axis activity. IL-1 enhances ACTH release, perhaps due to enhancement of CRH release, or by modulating the actions of other ACTH secretagogues. IL-2 augments POMC gene expression in the anterior pituitary and enhances ACTH release. The potent ACTH release by IL-6 may derive from stimulation of AVP release.

The HPA axis is highly stress responsive. Both physical and psychological stressors can cause increased activity of this hormone axis. In particular, novel stressors (stressors that are new experiences) cause HPA axis activation; with a person's repeated encountering of the stressor, there is less and less HPA axis response. This is particularly true of demanding tasks, which initially provoke an HPA axis response, but not after the person achieves mastery of the task through training and experience. Public speaking in front of a new audience can be a stressful experience to the novice but causes little or no stress, and therefore activation of the HPA axis, in the experienced speaker.

Increased ACTH secretion is also observed in pregnancy and at different periods during the menstrual cycle, because of the effects of estrogen in the circulation. Pathological (abnormal) function of the HPA axis can occur from several causes. These include repeated, uncontrollable environmental stressors, functional psychiatric illnesses such as major depression and schizophrenia, and disorders of the HPA axis itself, such as hormone-secreting tumors of the pituitary gland and adrenal cortex. Major depression is the best-studied psychiatric illness in this regard: 30–50% of major depressives have mildly to moderately increased HPA axis activity, consisting of increased blood concentrations of ACTH and cortisol at all times of the day and night, with preservation of the circadian rhythm of these hormones.

Negative Feedback Mechanisms

The mechanisms regulating ACTH secretion during stress are multifactorial, with the stimulatory effect of the hypothalamus, mainly from CRH and AVP, and the inhibitory influence of glucocorticoids. The HPA axis is regulated by two primary processes. One is closed-loop negative feedback of cortisol to hormone receptors in the hippocampus, hypothalamus, and pituitary gland. There are three types of closed-loop negative feedback systems. In the long-loop system, glucocorticoids exert a negative feedback on the anterior pituitary, hypothalamus, and hippocampus. In the short-loop system, ACTH itself feeds back on the hypothalamus, exerting negative feedback. In the ultrashort-loop system, the releasing hormone (CRH) acts directly on the hypothalamus to control its own secretion. All of these systems act to suppress the secretion of CRH, ACTH, and cortisol itself (Figure 3). The second primary process of ACTH regulation is open-loop driving of the HPA axis by the central nervous system (CNS) and by metabolic control of CRH secretion independent of glucocorticoids.

Figure 3 Examples of endocrine feedback mechanisms responsible for regulation of the HPA axis. The closed-loop negative feedback system is composed of the long, short, and ultrashort loops. The open-loop system includes both stimulatory and inhibitory inputs from the CNS that drive the HPA axis independently of closed-loop systems. The open-loop system also includes metabolic control of CRH secretion independent of cortisol. +, positive feedback or stimulation; –, negative feedback or inhibition.

Cushing's syndrome is a clinical condition resulting from chronic elevation of circulating glucocorticoids. Clinical signs and symptoms of Cushing's syndrome include obesity of the face and trunk, weakness and atrophy of limb muscles, increased blood pressure, imbalance of glucose metabolism, and psychological changes. There are two main types of Cushing's syndrome: ACTH dependent and ACTH independent. ACTH-dependent Cushing's syndrome results from increased pituitary secretion of ACTH, usually from a pituitary tumor (Cushing's disease), inappropriate ACTH secretion by nonpituitary tumors, often in the lungs, and inappropriate CRH secretion by non-hypothalamic tumors, in turn stimulating excessive pituitary ACTH secretion. These conditions, all involving excess ACTH production, cause enlargement of the adrenal glands and excessive cortisol secretion from continuous stimulation.

ACTH-independent Cushing's syndrome is caused by primary tumors or abnormalities of the adrenal cortex itself, resulting in excessive cortisol secretion and suppression of ACTH production by the pituitary. Prolonged administration of glucocorticoids for the treatment of certain illnesses also may cause ACTH-independent Cushing's syndrome.

The excessive pituitary production of ACTH and adrenal production of cortisol in Cushing's disease are only partially suppressible by low-dose dexamethasone, a synthetic and potent glucocorticoid, but are more suppressible by higher doses. In contrast, patients with nonpituitary sources of ACTH production will rarely show suppression of ACTH and cortisol by dexamethasone.

ACTH is released from the anterior pituitary in response to various stimuli, and its release is sustained or inhibited by intricate feedback systems, with ACTH at the center of this dynamic homeostatic system of loops. As part of the HPA axis, ACTH is considered one of the major stress hormones. It is now apparent that AVP and CRH cooperate as the major factors involved in the control of ACTH release.

 Exercise and Stress: Opposing Effects on Disease
 Risk Factors

Glossary

<i>Aerobic exercise</i>	Prolonged dynamic muscular work energized by the oxidation of food (fat, carbohydrates, and protein).
<i>Endogenous opioids</i>	A class of neuromodulators that can reduce pain and induce a positive (euphoric) mood.
<i>Heritability</i>	The heritability of a trait reflects the proportion of individual variation that can be attributed to genetic factors in a given population. Heritability of a trait can be obtained by comparing trait resemblance between monozygotic (MZ) twins that are genetically identical and dizygotic (DZ) twins that share on average only half of their segregating genes. A greater intrapair resemblance between MZ twins than between DZ twins in exercise behavior, for instance, reflects the contribution of genetic factors to exercise behavior.
<i>Insulin resistance</i>	Inability of tissue to respond to insulin mediated take-up of additional glucose. Insulin resistance is associated with increased risk for cardiovascular disease.
<i>Monoamines</i>	A class of neurotransmitters that are known to influence mood. Antidepressive medication is based on boosting the action of two monoamines (norepinephrine and serotonin) in the central nervous system.
<i>Stress reactivity</i>	The bodily response to the perception of threat or challenge. There is increased activity of the sympathetic nervous system

and decreased activity of the parasympathetic nervous system that becomes manifest as increases in levels of heart rate, blood pressure, and levels of stress hormones.

Sites of Interaction between Stress and Aerobic Exercise

This article reviews the evidence that regular aerobic exercise counters the detrimental effects of psychological stress. The hypothesized psychological, psychophysiological, and physiological effects of exercise are summarized in [Figure 1](#). In order to protect against psychological stress and stress-related disease, exercise is hypothesized to have the following effects: (1) improve psychological coping with stress, (2) reduce physiological reactivity to stress, and (3) counteract the dysregulatory effects of stress reactivity on disease risk factors.

Psychological Coping with Stress

Most of the research on the beneficial psychological effects of regular aerobic exercise has concentrated on improvements in well-being, often defined as the absence of negative affect, or on improvements in self-esteem and self-efficacy. Reducing negative affect, e.g., anxiety, hostility, or depression, decreases the chance that an event will be perceived as stressful (primary appraisal). Increasing feelings of self-efficacy increases the chance that coping skills are perceived to be adequate to deal with a stressful situation (secondary appraisal). Well-being and self-esteem further modify interpersonal behavior such that less conflict is generated, and they favor adaptive problem-oriented coping and social support seeking over detrimental coping strategies such as denial and social isolation. Thus, exercise-induced improvements in psychological coping with stress may decrease the number of situations that are perceived to be stressful. This will decrease the frequency and duration of physiological stress reactions mediated by the autonomic nervous system. That is important because such stress reactivity, when often repeated, is thought to give rise to physiological dysregulation and ultimately disease (see [Figure 1](#)).

Regular exercisers have consistently been found to show the iceberg profile: they have higher vigor (the peak of the iceberg) and lower levels of anxiety,

Figure 1 Hypothesized influences of aerobic exercise on the psychological and physiological effects of stressful events.

tension, apprehension, depression, and fatigue compared to nonexercisers. They are also found to be more outgoing, have greater self-esteem and self-efficacy, and score better on tests of coping skills. However, the coexistence of a healthy mind and a healthy body does not prove that the healthy mind is a consequence of the healthy body (such causality was never suggested by Juvenal, the Roman satirist who originated the adage of *mens sana in corpore sano* – he just prayed for both). The beneficial psychological makeup of exercisers in cross-sectional studies may be based on common underlying influences on both exercise behavior and psychological distress. These may be of a genetic origin, or they may reflect environmental influences such as low socioeconomic status and poor social support networks that affect both exercise behavior and psychological well-being. Most importantly, the association may reflect a reversed causality, namely, that emotionally well-adjusted, agreeable, and self-confident individuals with low levels of stress are simply more attracted to sports and exercise, or that only such persons have the necessary energy and self-discipline to maintain an exercise regime. In short, the favorable psychological profile of exercisers may reflect self-selection.

To prove that exercise can be used as a prophylaxis against stress and stress-induced disease, longitudinal training studies are needed. Such training studies must be carefully designed. Subjective expectations, distraction, social attention/interaction, and trainer enthusiasm must be separated from the effects of aerobic exercise per se. Therefore, the effectiveness of aerobic training must be compared to a placebo treatment, which may consist of stress management training, meditation, muscle relaxation, or a nonaerobic exercise program that aims to increase strength or flexibility rather than aerobic fitness. The subjects

must not be allowed to choose these treatments, but are randomly assigned to either aerobic training or control treatment to prevent self-selection of subjects with a specific psychological makeup or a relatively high aerobic endowment into the training group.

Several well-designed longitudinal studies have reported improved mood or reductions in coping behavior, depression, and anxiety after a program of aerobic exercise training in comparison to control manipulations. Unfortunately, many others have failed to replicate these training effects. The most promising evidence comes from studies in clinically depressed patients. These studies tend to report beneficial psychological effects of exercise that match or even exceed those of pharmacological treatment. Even in non-clinical populations, the training-induced changes in anxiety, depression, or self-esteem – when found – were generally largest in the subjects with the least favorable psychological profile before the start of the training. Without denying the potential of exercise as a therapy in subsets of subjects, most of the many reviews on this topic express only cautious optimism about the use of exercise for stress prevention in the population at large.

Psychophysiological Stress Reactivity

The various training-induced adaptations in the organization of the autonomic nervous system and its target organs, e.g., dominance of the parasympathetic over the sympathetic nervous system, greater sensitivity for hormonal cues (β -adrenergic receptors, insulin sensitivity), and better vascularization of muscle tissue, may all critically influence the pattern and intensity of physiological responses to stress, even if psychological coping with stress is unchanged. Although peak reactivity may not be influenced or even larger in exercisers, habituation during stress and recovery after stress may be faster, analogous with their physiological adaptation to bouts of exercise. An extensive set of studies has compared stress reactivity of well-trained exercisers with that of untrained nonexercisers. In about half of these studies, reduced stress reactivity and/or enhanced recovery was found in exercisers. The reverse was found only twice. Although these studies support the idea of lower stress reactivity in exercisers, they were mostly cross-sectional in nature. Consequently, self-selection factors and differences in endowment for fitness and/or psychological makeup, rather than exercise behavior, may explain the differences in reactivity.

Again, training studies yield the most meaningful answers. **Figure 2** provides an example of a typical design of a study to assess exercise training effects on physiological stress reactivity. In this study, four

Figure 2 A design for a training study (de Geus et al. (1993) *Psychosomatic Medicine* 55, 347–363) on physiological stress reactivity. The effects of the experimental manipulation are illustrated by the effects on resting heart rate.

groups of adult males took part in an aerobic training program consisting of two to three sessions weekly over periods of either 4 or 8 months. Control subjects were put on a waiting list for 4 months or remained untrained entirely. Some of the trained subjects were de-trained; after an initial 4-month training program, they had to abstain from intensive exercise for 4 months. The figure illustrates how the various manipulations were closely followed by changes in resting heart rate. The effectiveness of aerobic training was further measured by the peak oxygen consumption during a supramaximal exercise test, expressed as milliliters oxygen consumed per kilogram body weight (VO_{2max}). VO_{2max} is generally held to be the best indicator of aerobic fitness and is highly correlated to actual endurance performance (e.g., Cooper test or shuttle run). The average improvement in VO_{2max} amounted to 14% after 4 months and 16% after 8 months, which is the gain usually attained in long-term and intensive training programs. In spite of improved fitness, this study found no evidence of an effect of aerobic exercise training on an extensive set of physiological responses that included heart rate and blood pressure, stress hormones, indices of cardiac sympathetic and parasympathetic drive, and indices of peripheral vascular versus cardiac output responding. Stress reactivity tended to decrease over repeated measurements, but the decreases in reactivity were not affected by aerobic training or ensuing de-training. These results correspond fully with those of many other studies showing that aerobic training does not systematically reduce reactivity to stress or enhance recovery afterward.

Acute Effects of Exercise

Taken the meager experimental support from well-designed training studies, how can we explain the

commonly held belief in the stress-alleviating effects of exercise and the fact that many exercisers state to be motivated by stress reduction and increased psychological well-being? The source of this belief may be largely found in the acute psychological effects of exercise. In the training studies described previously, psychological and psychophysiological testing was preferably done when subjects had not been exercising for a few days. This was done to prevent confounding of the results by possible acute effects of exercise. Studies that have specifically addressed these acute exercise effects have provided evidence of improved mood, reduced feelings of tension, anxiety, and anger, and increased feelings of vigor directly after exercise. This acute feeling better effect of exercise is paralleled by various physiological effects. Although heart rate generally remains elevated above the base level, postexercise blood pressure is seen to decrease below base level for several hours. Neuro-muscular activity and peripheral pulse volume are decreased, and brain alpha activity, an indicator of a relaxed but alert mental state, is increased. Most importantly, there is evidence of reduced heart rate and blood pressure responses to stress in the hours directly after the exercise.

Among the hypothesized mechanisms for the acute psychological and physiological effects of exercise, those related to the endogenous opioids have been most often cited. An endogenous opioid, beta-endorphin, has been held responsible for the euphoric (after) effect of running, which has been ominously termed runner's high, and for a benign endorphin-mediated exercise addiction. However, elevations in peripheral beta-endorphin (a typical distress hormone often co-released with adrenocorticotropin) are seen only during strenuous exercise, not during mild to moderate exercise. More importantly, beta-endorphin levels are associated with negative mood, i.e., expectation of

future pain and exhaustion, rather than positive mood, even during exercise. Finally, the opiate antagonist naloxone does not prevent the exercise-induced elevation in the pain threshold or mood improvement, suggesting that these are largely independent of endorphin action. Since monoaminergic systems in the brain are involved in the pathogenesis of depression and anxiety, a more plausible explanation for exercise-induced mood effects may reside in its effect on central monoamines. Animal models suggest that exercising increases noradrenalin and dopamine metabolism in the brain and that it also increases brain serotonin content. It shares these effects with antidepressive like MAO inhibitors and serotonin-reuptake blockers. Beneficial effects on monoaminergic neurotransmission may also explain why improved mood after training programs is most often found in groups of highly anxious or depressed subjects. An improvement in monoaminergic neurotransmission may be effective only if it is severely compromised, as is the case in anxiety and depression.

Whatever the physiological and psychological causes, the tight contingency between exercise and the mood improvement directly afterward forms a solid basis for the popular belief that exercise relieves stress. Exercising may be an excellent short-term coping strategy that helps people to unwind more rapidly from daily pressures experienced in the school, job, or home environment, even if effects on mood are short-lasting. Likewise, the accumulation of episodes of blunted cardiovascular responsiveness may reduce the health risks of stress, even if reductions in stress reactivity are confined to stressors encountered in the postexercise periods.

For exercisers, exercising may become a major coping strategy, up to a point where stopping exercise could lead to loss of well-being and self-esteem. In fact, most of the popular ideas on the psychological benefits of exercise may stem from exercisers themselves. It must be noted, however, that in most Western countries only 10 to 15% of the population are engaged in exercise with high enough intensity (>70% maximal heart rate), duration (minimally 20 min), and frequency (three times a week) to maintain aerobic fitness level. About 60% have irregular exercise habits or perform mild exercise only, e.g., regular walking or bicycling. The remaining 25% are nearly completely sedentary, and this figure appears to be rather resistant to 50 years of campaigning to increase physical activity. A major future research question is why exercisers exercise and why nonexercisers do not.

Determinants of Exercise Behavior

Most of the research on the determinants of exercise behavior has focused on personality and social and

environmental characteristics, but increasingly innate biological mechanisms are considered as additional factors influencing the choice for exercise behavior. Recent studies on genetically related subjects have confirmed a large genetic influence on the choice for leisure-time exercise behavior in adult subjects, with heritability estimates as high as 85%. The influence of the exercise genes starts to appear in late adolescence. Two potential pathways for genetic influences to affect adult exercise behavior may be through personality characteristics (e.g., high sensation seeking or extraversion and low neuroticism) or physical fitness parameters (e.g., muscle strength, muscle endurance, and aerobic power) that are known to be highly heritable. We add the third possibility – which is not necessarily independent of the other two pathways – that exercisers, based on their genetic receptiveness, extract a larger benefit from exercise in terms of mood improvements and reductions in psychological stress reactivity. Earlier we tacitly assumed that such effects are identical in all subjects, whereas in fact gene–environment interactions are highly likely to occur. Subjects who are genetically more favored by psychological and stress reactivity benefits may find it easier to become lifetime regular exercisers than those who do not experience similar benefits or even suffer from the added burden of having to do something that mainly feels unpleasant. This gene–environment interaction means that the group differences seen in cross-sectional comparisons of long-time exercisers with persistent sedentaries will not be recaptured by the pre- to posttraining differences found in experimental training studies. The group of long-time exercisers will be biased to include only the most receptive subjects. *Mutatis mutandis*, it also means that true beneficial effects for genetically receptive subjects in the studies on psychological coping and psychophysiological stress reactivity cited previously may have been snowed under by null (or negative) effects in those subjects who are genetically less receptive (or even vulnerable).

Exercise and Stress: Opposing Effects on Disease Risk Factors

A final interaction between stress and exercise can be found at the level of disease risk factors, where exercise may systematically oppose the physiological impact of repeated stress reactivity. Evidence for such an interaction comes from the field of cardiovascular disease. Chronic stress is thought to negatively influence a set of atherogenic factors such as high low-density lipoprotein (LDL) (bad) cholesterol, low high-density lipoprotein (HDL) (good) cholesterol, high triglycerides, high insulin, high heart rate and

Figure 3 Beneficial effects of 4 and 8 months of aerobic exercising on a cluster of risk factors that are suspected to be affected by psychophysiological stress reactivity: percentage body fat; plasminogen activator inhibitor (PAI-1) activity, a risk indicator for disturbances in the coagulation–fibrinolysis balance; triglycerides; ratio of LDL (bad) to HDL (good) cholesterol; and ambulatory diastolic blood pressure.

blood pressure, and a disturbed balance in the coagulation and fibrinolysis of the blood. This cluster of risk factors is a common clinical finding that is not constituted at random but is the multifaceted symptom of a basic abnormality, called insulin resistance syndrome, rooted in overweight and inefficiency of the (muscular) tissue to take up glucose. These risk factors affect the integrity of the arterial walls in synergy, such that stress-induced increases in levels in one of these parameters increase the pathogenic effect on all of the others.

A few hours of exercise per week is known to be able to counter all these detrimental effects. Although no effects on stress reactivity (task minus baseline) are found, virtually all training studies show a decrease in absolute levels of heart rate and diastolic blood pressure during baseline and stress conditions. This effect is completely reverted after de-training, which strongly argues for a causal effect of exercise. Ambulatory studies have confirmed that the significant decrease in heart rate and blood pressure remains intact in naturalistic situations. In addition, regular exercise reduces the LDL/HDL cholesterol ratio and triglyceride levels, increases fibrinolytic potential of the blood, and does so most likely through preventive maintenance of muscular insulin sensitivity. [Figure 3](#) shows some of the simultaneous beneficial effects on various risk factors using data from the 4- and 8-month training programs described in [Figure 2](#).

In conclusion, aerobic exercise should be seen as an excellent way to compensate for or prevent

stress-related deterioration of cardiovascular health, even if psychological makeup or the acute reactivity to stress is unchanged after months of training. These health benefits suffice to strongly encourage the promotion of aerobic fitness programs to compensate for the aversive effects of daily stress.

A Note on Nomenclature

Glossary

<i>Affect</i>	Objective manifestations of emotional state, including facial expression, demeanor, neurovegetative functioning, and behavior, but also verbal statements reflecting mood, self-attitude, and vital sense.
<i>Disease</i>	A clinical syndrome with characteristic signs and symptoms, related to dysfunction in a bodily organ, caused at least in part by biological forces.
<i>Mood</i>	Sustained subjective emotional state.

Neuro-vegetative functioning
Psychosis

Motivated behavior essential to biological functioning, including sleep, appetite, and libido.

Severe symptoms of mental illness involving dysfunction in rational thought and reality testing, including hallucinations and delusions.

Self-attitude

Feelings of personal worth, ranging from grandiosity to self-loathing.

Vital sense

Feelings of physical well-being, including energy, clarity and speed of thought.

Affective disorders are psychiatric syndromes characterized by significant disturbances in mood, the sense of self-worth, and the feelings and functions of physical well-being. Affective disorders can lead to occupational and interpersonal impairment and often (perhaps not often enough) the pursuit of treatment. Suicide is an all-too-common outcome of a severe affective disorder. Major depression, according to the United Nations World Health Organization, is the second leading cause worldwide of lost years of health and productivity. Mood swings routinely wreck marriages and careers and trigger and sustain substance abuse. The clinical features, management, and biology of mania and major depression are described elsewhere in this work; therefore, the present article examines the concept of affective disorders from the multiple perspectives of phenomenology, meaning, behavior, and temperament to complement the growing biological understanding of these disorders.

Phenomenology of Affective Disorders

The clinical syndrome of all affective disorders is a persistent and pervasive disturbance in mood, self-attitude, vital sense, and neurovegetative functioning. In depression, the varieties of mood disturbance include not only melancholia or sadness, but also apathy, anxiety, and irritability. Some patients describe depression as the absence of any feeling. The mood of a manic patient may be elated, but also irascible to the point of belligerence, expansive without a sense of euphoria, or simply excitable.

Self-attitude, the feeling of personal worth, is insidiously disturbed in affective disorders. The disturbance in self-valuation often impedes treatment. Depressed patients may delay treatment because the suffering they experience seems somehow deserved; ultimately suicide may be desired because the patient feels that he or she is such a burden on others. Manic patients may feel smarter than the doctor and others, and may feel misunderstood or insulted by the suggestion they are ill.

Affectively ill patients have a disturbance in the sense of physical well-being, or vital sense. In depressed patients, physical well-being is lacking; patients feel tired, weak, slow, and inept; cognition is halting or uncertain. Manic patients tend to feel energized, quick, tireless, and powerful. Thoughts move swiftly; the patient may have the sense that he or she is thinking circles around others, while others may find the patient's ideas loose, connected by the thinnest of associations – clanging speech, riddled with puns and rhymes, is seen in severe cases – or at the most severe, incomprehensible. Neurovegetative functioning – the body's internal regulation of activity and metabolism – is typically disturbed in both syndromes. Depressed patients may have insomnia or may sleep to excess without feeling rested. Manic patients may feel little to no need to sleep and may arise rested after a few hours and carry on in this manner to the marvel (or annoyance) of others. Appetites tend to diminish with depression (though some will overeat or binge); in mania the drive for food is less often disturbed, but the drives for sex, acquisition, and excitement are enhanced.

Affective disorders are diagnosed from clinical history and observation of the patient's demeanor and behavior. The clinician is more certain of the diagnosis upon hearing the patient's own description of troubling mental phenomena and personally observing signs (e.g., emaciation, lethargy, agitation, rapid speech) consistent with the clinical syndrome. There are no laboratory tests to reveal affective disorder.

The Experience of Affective Disorders

Literature abounds with poignant and gritty descriptions of what it is like to be manic or depressed. A pervasive theme in these descriptions is the relative inability of a person in the grip of a severe mania or depression to perceive that the accompanying attitudes, responsiveness, and emotional states are pathologically disconnected from or disproportionate to the true circumstances. A depressed mood, sleepless nights, lack of appetite, feelings of worthlessness, and wishes for death often seem to a depressed patient to follow inevitably an unwanted change in life such as a divorce or job loss. A profound sense of meaninglessness is attributed to the world, rather than to the patient's altered perception of the world. The elated mood in mania seems to the inexperienced patient to be the natural consequence of possessing superhuman energy and confidence. The heightened sense that everything is possible seems a quality of the world, in the eyes of the manic patient, and not a distortion driven by an abnormal mood.

Insofar as depressive and some manic states are unpleasant, patients generally understand them to be a response to stress, with the implied assumption that they have had a nervous breakdown because they were unable to handle the stress. On being diagnosed with an affective disorder, many patients are relieved to hear their distress attributed to a medical illness or chemical imbalance in the brain, especially when told of the successful record of biological treatment. Patients with repeated episodes of mania and depression eventually come to see the disease as a primary problem, rather than a secondary result of life circumstances. It begins to seem more plausible that, while some episodes may certainly have followed a significant change in life circumstances, others were unprovoked, or even preceded a change in circumstances; indeed, it may occur to the experienced patient that the changes were in some cases caused by the affective disorder. Was a patient's emotional state so inconstant that romantic partners found the relationship intolerable? Did a drop in energy and motivation result in an unfavorable change in job status, which heralded a suicidal episode? Did a patient feel elated because of a vacation in the tropics, or did the motivation to travel stem from a markedly heightened capacity for excitement, pleasure, and financial largesse?

Thus, the general question of whether stress causes affective instability or affective instability causes stress cannot be answered definitively by asking the patient, as the illness distorts the patient's ability to tell the difference. This is one fundamental difference between

an affective disorder and a disorder of the visceral or peripheral organs: in the latter case, the intact mind, seated in the brain, receives unambiguous information from another organ about a disease process, e.g., pain, shortness of breath, weakness. With affective disorders, the major symptoms are in the mind, where they impede perceptions and judgments.

Behavior in Affective Disorders

From the perspective of a family member or treating clinician, the most salient features of an affective disorder are the behavioral difficulties it drives. Most alarmingly, affective disorders often drive self-destructive behavior. The vast majority of suicide victims can be diagnosed, in retrospect, with affective disorder. When the suicidal behavior does not result in death, it nevertheless may permanently strain relationships with those the patient intended to leave behind.

Suicide is the direst behavioral outcome of affective disorder, but not the only significant maladaptive behavior. At the core of maladaptive, affectively driven behaviors is the change in hedonic capacity that typically accompanies them. Where reward is absent, as in the anhedonic, depressed patient, experiences may seem flat and meaningless, and in many cases painful and enervating. A depressed patient may withdraw to bed, avoid family, friends, and work, and seek solace in alcohol or drugs. When reward comes too easily or powerfully, as in mania, the impulse to spend, drive, and love recklessly, to flout the law and social mores, and to abuse alcohol and drugs is nearly irresistible. For the manic patient there is an indiscriminate sense of excitement over a world of newly perceived opportunities for enjoyment, resulting in costly, uninhibited, social and financial decisions.

It is important to note that affective disorders are not essential in such behaviors. Many people who attempt suicide, avoid work, spend recklessly, or drink heavily lack the signs and symptoms of affective disorders. Many patients with affective disorders (perhaps most) manage, somehow, to constrain their behavior. Patients who change their behavior in the midst of an episode of affective disorder may benefit from confrontation and counseling about the consequences of their behavior. Some therapists think of the self-defeating and self-deprecating thoughts and attitudes that arise during depression as behaviors amenable to confrontation and redirection; this idea is the basis of cognitive therapy.

The degree of behavioral impairment associated with affective disorder can be a function not only of the severity of the symptoms, but also of the vulnerability of the patient to behavioral excess or instability.

A libertine when stable is more likely than a saint to engage in reckless acts when affectively ill, if only because the means to such acts are more familiar. An academically and economically marginal college student knocked out of school by affective illness may have a harder time getting back on track than a middle-class mid-career middle manager in a solid marriage. A student not only lacks the benefit of a structured life upon which to recover, but may also have the option unavailable to the older person of re-entering a state of dependency on parents, a state that may reinforce functional debilitation. Patients and families are wisely counseled not to make major changes in career, family, or housing in the midst of an episode of mania or depression. The fewer the changes, the less the risk of serious impairment, and the easier the rehabilitation once the episode clears.

Affective Disorders and Personality

Greater symptom severity may drive one patient's behavior to go awry while a less afflicted patient remains relatively steady, but personality and life circumstances also contribute. Some affectively ill patients prone to dysfunctional behavior may have personality disorders at baseline. Personality disorder refers, in diagnostic nomenclature, to enduring patterns of temperamental vulnerability and problematic behavior. These disorders may themselves be defined by their affective components, e.g., the labile affect of the borderline patient or the constricted affect of the schizoid patient. Thus, it can be hard to tell if a patient who seems to meet diagnostic criteria for a personality disorder really has an affective disorder. Patients in a manic state often display labile affect and indifference to the feelings of others (and other borderline or narcissistic traits), and depressed patients often appear cold and constricted. Thus, it is generally prudent to wait to assign a definitive personality disorder diagnosis to an affectively ill patient until after the affective syndrome clears up and the patient can be observed in the well state.

The concept of affective disorder also becomes salient when considering individuals who seem characterologically gloomy, moody, or excitable. Although they are counted as having mild forms of affective disorder, the existence of chronically gloomy (dysthymic) and chronically moody (cyclothymic) individuals illustrates the permeable boundaries between entities considered as medical disorders versus those understood as features of character or temperament. Indeed, affective and personality disorders may not be fully independent in their origins. It seems plausible to assume that childhood or adolescent onset of affective disorder is likely to result in persistent – even

permanent – changes in the direction of personality development. Whereas affectively stable individuals learn through experience to properly associate their behaviors with desired social and interpersonal consequences, the experience of affective disorder, which warps these affective connections during critical stages of adult development, may lead to the sort of immature emotionality and self-defeating behavior that characterize the personality disorders.

Varieties of Affective Disorder

There are many ways to categorize affective disorders. The most salient clinical distinction is between manic-depressive and melancholic (depressive) disorders. Modern nosology refers to these disorders as bipolar disorder and major depressive disorder. Beyond the differentiation by polarity, affective disorders are classified according to severity and chronicity. [Figure 1](#) illustrates the spectrum of affective disorders, ranging from mild, transient normal mood fluctuations to severe, rapid-cycling bipolar disorder type I.

In clinical reality, the differentiation of mania from depression is not always so clear. Many patients experience either a mixture or the rapid alternation of manic and depressive symptoms. One way to understand these mixed states (following Kraepelin) is to postulate that there are different components of affect (we might call them mood, cognition, and energy) that tend to cycle in synchrony during typical manic (high mood, rapid and copious thoughts, high energy) and depressive (low mood, sluggish and paltry thoughts, diminished energy) episodes, but that synchrony is lost in mixed states ([Figure 2](#)). A patient in a common presentation of mixed state will tend to have a dysphoric (irritable, nihilistic) mood but such racing thoughts and restless energy that the patient will appear irascible and feel highly uncomfortable. In practice, the mixed state is seen as a high-risk state for suicide. In contrast, a patient with agitated depression combines dysphoric mood with restless energy and a poverty of thought, generally manifested as a tendency to ruminate on a single, depressive theme. Other combinations, in particular those involving euphoric mood without high

Figure 1 Affective disorder diagnoses as a function of the frequency and amplitude of mood variability. Note that normal mood changes may be frequent but are mild and transient, while the more severe mood swings tend to last weeks, months, and in the case of dysthymia, years.

Figure 2 Kraepelin's schema of mixed affective states. The coexistence of a morose mood (low emotion) with physical restlessness or agitation (high volition) and racing thoughts (high intellect) creates a typical mixed state.

energy, seem more rare, though it may be that these patients are rarely brought to treatment.

History of the Concept of Affective Disorders

Descriptions of melancholia and mania date back to Hippocrates, and many medical writers throughout history were able to describe the manic-depressive syndrome in a way familiar to modern psychiatrists. Until the nineteenth century, the prevailing explanations for affective disorders relied on the humoral theory. Abnormal balances of bodily fluids such as black bile (the roots for the term melancholia) or yellow bile (an excess of which was associated with the choleric, or irritable, temperament) were felt to be the cause of affective imbalance.

By the nineteenth century, ideas about the organic basis of disease had become more sophisticated, and observations of psychopathology were made systematically with the view that affective disorders had their basis in an as-yet-unknown disease of the brain. An exemplar of this trend was Emil Kraepelin, who delineated the patterns of symptoms and course in the institutionalized severely mentally ill under his care. Kraepelin noted a general difference in the course and affective symptomatology in the two groups of patients: those having a remitting/relapsing forms of psychosis marked by prominent signs of affective disturbance, and those having a chronic psychosis with affective flattening. Kraepelin called the remitting/relapsing disorder manic-depressive insanity and the chronic

psychotic conditions paranoia (including dementia praecox, now better known as schizophrenia).

Psychiatric epidemiologists have established that affective disorders are not only found in the severely, institutionalized mentally ill, but also are fairly common in the general population. About 1 in 100 individuals in population surveys meet diagnostic criteria for bipolar disorder, and 5–10% have a major depressive episode at some time in life. Many patients with affective disorders do not develop psychosis or require hospitalization; a rather large percentage never enters treatment.

Historical accounts of the obviously manic and melancholic are not too hard to find; it is harder to account for the large number of those who, it is supposed, experienced milder forms of mania and depression but understood these experiences in non-medical terms. Traces of these experiences perhaps are found in the annals of art, literature, politics, business, philosophy, exploration, science, and religion, where a mild depression in a receptive mind may produce enduring insights about the fragility of existence or tenderness to the suffering of others. Mild manic states may have contributed to expansive works of art or ambitious, risky exploration and entrepreneurship. Affectively colored cultural contributions are not necessarily pathological, though the experience of the passionate, creative, or daring historical figure might resemble in detail the experience of a typical patient with an affective disorder. It is just as possible that the availability of effective anti-depressive and antimanic treatments in times past

might have robbed the world of some works of genius as it is possible that the geniuses themselves might have been spared much suffering and contributed even more had treatment been available.

Affective Disorders as Diseases

Efforts to link affective disorders to external circumstances have yielded distinctions between mourning and melancholia (Freud), and reactive versus endogenous depression. But if it is unclear whether stress causes depression or vice versa, then a simpler, assumption-free explanatory model is required if we are to understand the normal dejection that results from, say, a romantic setback, versus the prolonged sadness that accompanies the grieving process, versus a pathological affective disorder. Unlike emotional reactions, affective disorders are clinical syndromes with stereotypical patterns of sign, symptoms, course, and treatment response. Unlike grieving, affective disorders are associated in some cases with known brain disease. Affective disorders are best understood as medical diseases, i.e., as syndromal entities emerging from biological dysfunction in the brain and body.

Like other medical diseases, affective disorders are not limited by culture, intelligence, education, socioeconomic status, or experience. Nor do the symptoms of affective disorder vary much across cultures, although one might expect to see culturally and individually specific manifestations of these symptoms. The typical symptoms of affective disorder cluster over a similar course and respond to the same biological treatments anywhere in the world. Affective disorders, moreover, may arise from known medical causes. Huntington's disease, a genetic disorder of progressive dementia and abnormal movement, carries a high risk for manic-depressive disorder. Some patients develop their first depression after a stroke (particularly a stroke in the left frontal part of the brain). Certain medications can cause a clear depressive syndrome; knowledge of the pharmacology of such drugs spawned research into medications to reverse the depressive syndrome. Cortisol-like drugs (e.g., prednisone) frequently induce manic symptoms in people with no history of affective disorder. If such known changes to the anatomy and biochemistry of the brain can trigger the characteristic signs and symptoms of affective disorder, then it seems reasonable to conclude that the commonly observed affective disorders arise from biological mechanisms as yet unknown, but knowable.

In contrast, clinical problems related to mood alone are strongly culture bound and uniquely expressed, generally have few if any symptoms other than a bad mood, and cannot be mimicked by drugs

or other medical diseases. Unpleasant or unmanageably intense mood reactions of this sort are best viewed primarily as discouragement, demoralization, the blues, or in the official nomenclature, adjustment disorders. Grief, on the other hand, has a syndromal quality to it, with characteristic sensations: the welling-up feeling, the false recognition of the departed in a crowd. Uncomplicated grief is not a disease, of course, but a normal part of human experience: painful, but rich with personal meaning. In real clinical situations, it is not always simple to distinguish grieving from moping from depression, but it is essential to try.

Affective versus Other Psychiatric Disorders

Patients with affective disorder often seem superficially to have other sorts of psychiatric illness, and vice versa. While affectively ill patients may demonstrate cognitive dysfunction (poor attention and concentration in depression, disorganization and distractibility in mania), mania and depression are not a cognitive disorder, like dementia, since the cognitive difficulties tend to clear up with normalization of the mood. In contrast to a chronic psychotic disorder such as schizophrenia, psychotic symptoms in patients with affective disorder tend to occur only when the patient is in the grip of severe mania or depression. In practice, however, the boundaries of affective and psychotic disorders are not always well defined. Some believe that schizophrenia and bipolar disorder have the same cause, with schizoaffective disorder as an intermediate type; it seems more likely that both disorders have complex causes and that some of these causes affect the presentation and course of illness in either disorder. Anxiety disorders, too, may be related to affective disorders; indeed, anxious moods, phobic avoidance, panic disorder, and obsessive-compulsive disorder are seen frequently in patients with affective disorder. Anxiety disorders share some of the characteristic symptoms of affective disorders: disturbances of mood and physical well-being, but miss the typical affective disturbances in self-worth, sleep, and appetite.

In summary, affective disorders are fairly common and often severe medical diseases afflicting mood, self-attitude, vital sense, and the bodily functions of sleep, appetite, and libido. Some patients exhibit marked changes in behavior, while others maintain the appearance of normality despite their symptoms. Although a patient with an affective disorder (and loved ones and caregivers) will often search for a meaningful explanation for the symptoms, the source of the problem is likely to be in the functioning of the brain. Stress may trigger the onset of an affective

disorder in a vulnerable individual; affective disorders certainly cause stress. Patients with affective disorders require not only biological treatment of the disease, but also management of self-destructive behavior and rehabilitation once the episode clears.

A Note on Nomenclature

Strictly speaking, there is no longer a universally accepted set of “affective disorders”. Earlier generations of psychiatrists spoke of manic-depressive reactions, depressive neuroses, and affective psychoses, which melded into the category of affective disorders in the *International Classification of Diseases*, 9th edition (ICD-9), in 1975, and in the *Diagnostic and Statistical Manual*, 3rd edition (DSM-III) in 1983. Subsequently, although the list of disorders included in the category remained more or less constant, the labeling in both classification schemes changed from “affective” to “mood” disorders in their next editions. The significance of this change in terminology is hard to estimate, as the definitions of affect and mood vary from source to source. Taking the prevailing view that affect encompasses mood along with its various associated qualities, the term affective disorders is preferred in a discussion of the conceptual foundations of these disorders, as it seems more descriptive. All of the disorders counted as mood disorders in current diagnostic schemes are disorders of much more than the prevailing emotional state, while in any given patient, change in the mood itself may be a minor

problem compared to changes in energy, motivation, and neurovegetative functioning.

Psychosocial Factors in Aggression

Biology of Aggression

Psychopharmacology of Aggression

Glossary

Antisocial behavior

Behavior in which the rights of others are violated; includes behavior that provides grounds for arrest, deceitfulness, failure to honor obligations, lack of remorse, and irritability and aggressiveness against people and property (i.e., vandalism).

Criminal behavior

Behavior in which a crime is committed, usually behavior that is identified by the criminal justice system.

Delinquent behavior

Antisocial behavior seen in children and adolescents, including aggression and other dysfunctional behaviors (e.g., school truancy).

<i>Epidemiological survey</i>	A study in which a representative sample of a population of individuals is studied to estimate the number of individuals from that general population that have a certain condition or diagnosis.
<i>Functional magnetic resonance imaging (fMRI)</i>	fMRI is the abbreviation for functional magnetic resonance imaging. fMRI allows imaging of brain-related activity in response to human subjects involved in cognitive or emotional tasks.
<i>Genetic studies</i>	Studies that are designed to estimate whether a condition or disorder has an underlying genetic component. These include family studies, which can show whether a condition runs in families; twin studies, which can show whether a condition is more likely to occur in identical than in fraternal twins and therefore must have a genetic component; and adoption studies, which can show the separate and interactive contributions of environmental and genetic factors.
<i>Heritability estimate</i>	A mathematical estimate of the magnitude of the importance of the role of genetic factors in a condition or disorder.
<i>Neurochemistry</i>	The aspect of biological functioning related to chemicals that transmit neuronal signals from one nerve to another.
<i>Norepinephrine (NE)</i>	NE is the abbreviation for norepinephrine, one of the main monoamines in the brain. NE is widely distributed in the brain and is involved in mediating a variety of brain and behavioral functions including, but not limited to, arousal.
<i>Problem solving</i>	The ability to find solutions to everyday types of problems.
<i>Psychosocial influences</i>	Potential influences on behavior (or on conditions/disorders) that are not apparently due to genetic or biological factors.
<i>Serotonin (5-hydroxytryptamine, 5-HT)</i>	5-HT is the abbreviation for serotonin, one of the main monoamines in the brain. 5-HT is widely distributed and is involved in mediating a variety of brain and behavioral functions including, but not limited to, behavioral inhibition.
<i>Transgenerational studies</i>	Studies comparing different generations (e.g., grandparents, parents, and offspring).
<i>Violent behavior</i>	Behavior in which physical aggression in some form is present.

Types of Aggression

Aggression can be defined as intentional act committed by an individual that has the potential to result in the physical or emotional harm of a person or of an object. Although aggression is typically thought of

as constituting a physical assault, acts of aggression also include verbal outbursts in which the individual's voice is used to convey anger in an uncontrolled manner. Broadly speaking, aggression can be subdivided into two types: impulsive aggression and premeditated or nonimpulsive aggression. Aggression is impulsive when the aggressive act is unplanned or in response to an aversive stimulus, generally uncontrolled, and committed without the expectation of achieving a tangible objective. By contrast, premeditated aggression is controlled, involves planning, and is associated with an expectation of reaching a specific goal such as, for example, the intimidation of the victim. Although acts of impulsive aggression can sometimes be criminal in nature, premeditated aggression is more likely to occur in the context of other criminal behavior. Because impulsive, rather than premeditated, aggression appears to be associated with specific biological and pharmacological response characteristics, this review focuses on impulsive aggression.

Epidemiology of Aggression

Despite the clinical importance of impulsive aggression, there is very little epidemiological data specifically regarding impulsive aggressive behavior. Existing epidemiological data exclusively refer to homicide and physical assault (i.e., aggression in general). Currently, the age-adjusted rate for homicide in the United States, based on vital statistics records, is 0.01%. Epidemiologic survey data find that approximately 25% of all males report a history of some physical fighting since 18 years of age, a rate that is twice as high as is found in adult females. Accordingly, approximately 10–15% of the general population report that they have engaged in physical fighting as an adult. This proportion translates into at least 25.0–37.5 million individuals in the United States alone. Although we cannot know what proportion of homicides or physical assault were impulsive in nature, it is likely that a substantial proportion represent impulsive aggressive acts.

Genetics of Aggression

Data from twin, adoption, and family studies support the hypothesis that aggression is under significant, if variable, genetic influence. The differences seen in these results are due, most likely, to the fact that different studies examined aggression in different ways using differing assessment measures. Specifically, aggression has been examined in these types of studies by using categories that more or less reflect aggression (such as delinquent behavior, antisocial behavior, criminal behavior, and violent behavior)

in populations with psychiatric diagnoses or by using scales that more or less reflect the severity of aggression in the general population or in university students. In clinical populations, genetic influences appear to underlie both delinquent behavior and antisocial behavior. In general populations, heritability estimates for measures of aggression range from substantial in children to moderately substantial in adults (44–72%) to apparently nonexistent in adolescents. Most noteworthy is the observation that the aggression measures with the greatest heritability estimates reflect anger and hostility and/or anger, impulsiveness, and irritability. These are the type of behavioral traits that appear to be associated with impulsive aggressive behaviors and that, in turn, have been shown to be strongly correlated with biological factors and with psychopharmacological responses to treatment with anti-aggressive agents.

Psychosocial Factors in Aggression

The most important psychosocial factors involved in the development of aggression appear to be low socioeconomic status (SES), ineffective parenting style, physical punishment during childhood, and exposure to aggression in- and outside the family. Factors involved in maintaining aggression appear to be the poor development of problem-solving skills, a bias to attribute hostile intent to others, and a deficiency in appropriately detecting environmental and social cues.

Low Socioeconomic Status and Parenting Style

Low SES has been linked to the development of aggression in numerous studies. However, it is likely that low SES exerts its effect on aggression through more relevant behavioral factors such as being raised in a criminally violent family and exposure to gang activity and violence. The stress associated with poverty is associated with negative parental interactions and, consequently, parental irritability, a factor that was associated with aggressiveness in children. More specifically, marital problems in low-SES families has been linked to aggression in children. In addition, an association between lack of maternal responsiveness (and poor child rearing) in low-SES homes and aggressiveness has also been reported, a finding consistent with earlier reports showing that nonnurturing parents tend to have aggressive children. A critical predictor in this regard appears to be the lack of favorable warmth toward the children. This factor appears to be associated with the impairment of effective parenting so that children in these families do not fully internalize the difference between right and wrong.

Exposure to Violence

Exposure to violence both inside and outside the home has also been linked to aggression. Physical punishment and child abuse has also been associated with the development of aggression in children. In transgenerational studies, parents who behaved aggressively toward their children had aggressive children who, in turn, raised similarly aggressive children. Harsh discipline and child abuse (regardless of SES) appears to specifically predict the development of impulsive, but not nonimpulsive, aggressive behavior in children. Witnessing aggression has also been associated with the development and instigation of aggression, and it is likely that the presence of aggressive environmental cues may increase the immediate risk of aggression in susceptible individuals.

Deficiency in Problem Solving

A deficiency in problem-solving skills has been noted to be involved in the maintenance of aggression in impulsive aggressive children in particular. Impulsive aggressive children tend to have interpersonal problems and often get rejected by their peers. Although aggressiveness may appear to be a prime reason for peer rejection, cognitive factors may also play a role in this regard. Specifically, aggressive children tend to attribute hostile intent to others with whom they are interacting. It is important to note that the attribution of hostile intent to others may act as the provocation for an aggressive encounter. This hostile attribution is specific to their own interactions; these children do not attribute hostile intentions to other children with whom they are not interacting. The tendency of aggressive children to attribute hostile intent to others may be related to the observation that aggressive children, specifically impulsive aggressive children, have difficulty reading relevant social cues. For example, impulsive, but not nonimpulsive, aggressive children have been found to incorrectly label a visual cue (i.e., a sad face is identified as reflecting another emotion).

It is important to recognize, however, that these various psychosocial factors demonstrate a variable association with aggressive behavior. Like genetic factors, psychosocial factors can only predict aggressiveness as a probabilistic function of who may become aggressive given the presence of other factors. Clues to understanding this finding may be found in examining the role of biology in aggressive behavior.

Biology of Aggression

Among the constitutional/developmental biological factors possibly involved in aggression, the most

studied factors relate to brain neurochemistry, specifically to monoamines such as serotonin (5-HT) and other centrally acting neurotransmitters.

Serotonin

The evidence for a role of brain 5-HT in human aggression is especially strong. In fact, the inverse relationship between impulsive aggressive behavior is the most consistent of all findings in biological psychiatry. Various measures reflecting brain 5-HT function have been shown to correlate inversely with life history, self-report questionnaire, and laboratory measures of aggression. Most notable is the replicated observation that evidence of reduced central 5-HT is present in impulsive, but not premeditated, aggressive subjects. This indicates that impulsive aggressive behavior can be distinguished biologically from nonimpulsive aggression and, accordingly, is a valid subtype of human aggressive behavior. An inverse relationship between 5-HT and aggression is reported in most, although not all, studies. However, when studies are at variance with this basic finding, issues related to sample populations probably account for the differences in reported findings.

Nonserotonin Systems

Catecholamines and vasopressin Although there are less data available to support the role of non-5-HT brain systems and modulators in human impulsive aggression, there are limited data suggesting a facilitatory role for catecholamines (i.e., dopamine and NE) and vasopressin in impulsive aggressive behavior. The relationship of catecholamines and vasopressin to aggression and serotonin, specifically, is noteworthy. In the case of the catecholamines, the typically inverse relationship between aggression and 5-HT may not be seen when catecholamine system function is reduced. Accordingly, correlations between measures of 5-HT and aggression are generally absent in depressed subjects, who typically demonstrate diminished NE system function. In the case of central vasopressin and aggression, 5-HT appears to be inversely related to both central vasopressin and aggression in both animal and human subjects. In human subjects, the relationship between central vasopressin and aggression is present even after vasopressin's relationship with 5-HT is accounted for. In animal studies, both central vasopressin activity and aggression can be suppressed by treatment with selective serotonin reuptake inhibitor (SSRI) agents.

Testosterone and cholesterol In addition to non-5-HT central neurotransmitters, at least two peripheral substances appear to have a relationship with

aggression. Based on data from both animal and human studies, testosterone appears to have a facilitatory relationship with aggression. The relationship among testosterone, aggression, and 5-HT is less clear, although chronic testosterone exposure appears to downregulate central 5-HT receptors in some studies.

Another peripheral, although centrally active, substance that appears to influence aggressive behavior is cholesterol. Over the past decade, data from a variety of studies suggest that a reduction in circulating levels of cholesterol may be associated with an increase in aggressive behavior in both human and animal subjects. Although a link to 5-HT has not been conclusively demonstrated in human subjects, studies in nonhuman primates clearly demonstrate that a reduction in circulating cholesterol levels is associated with a reduction in measures that reflect central 5-HT function.

Localization of Biological Abnormalities

Reductions in cerebrospinal fluid (CSF) levels of neurotransmitter metabolites (e.g., 5-HIAA) suggest a central location for alterations in biological systems. However, CSF metabolites cannot reflect abnormalities in specific locations. Abnormalities in hormonal responses to pharmacological challenge agents do suggest an abnormality in the hypothalamus (a part of the limbic system involved in the regulation of emotion and behavior) of impulsive aggressive individuals. Recent clinical neuroscience and brain-imaging studies have reported data suggesting the hypofunction of parts of the prefrontal cortex and relative hyperfunction of deeper subcortical structures. For example, fluorodeoxyglucose positron emission tomography (FDG-PET) scan data demonstrate lower metabolic rates bilaterally in the lateral and medial areas of the prefrontal cortex of impulsive, but not premeditated, murderers than in normal controls. In contrast, the metabolic rates of subcortical structures (e.g., hippocampus, amygdala, thalamus, and midbrain) in the right hemisphere were found to be elevated in both impulsive and premeditated murderers compared with normal controls. More recent data from fMRI studies suggest a dysfunction of the amygdala-orbital prefrontal cortex such that there is greater activation of the amygdala and less activation of the orbital frontal prefrontal cortex. Because prefrontal structures are thought to regulate inhibition and subcortical structures, such as amygdala, are thought to regulate arousal, these data suggest that impulsive aggressive individuals have, compared to normal controls, less prefrontal inhibition in the context of greater subcortical emotional drive. Premeditated aggressive individuals, by contrast have

normal prefrontal inhibition but greater subcortical emotional drive. These data, in addition to the neurotransmitter-specific data already discussed, suggest that aggression in impulsive aggressive individuals can be treated by strategies that increase prefrontal inhibitory mechanisms and reduce subcortical facilitatory mechanisms.

Psychopharmacology of Aggression

As might be expected from the results of the biological study of aggression, several psychopharmacological agents appear to have anti- or pro-aggressive effects. The classes of agents shown to have anti-aggressive effects in double-blind, placebo-controlled trials include mood stabilizers (e.g., lithium), 5-HT uptake inhibitors (e.g., fluoxetine), anticonvulsants (e.g., diphenhydantoin, carbamazepine, and depakote), and NE beta-blockers (e.g., propranolol and nadolol). The classes of agents that may have pro-aggressive effects include tricyclic antidepressants (e.g., amitriptyline), benzodiazepines (e.g., alprazolam), and stimulant and hallucinatory drugs of abuse (e.g., amphetamines, cocaine, and phencyclidine). The most notable findings from the relatively small literature of the double-blind, placebo-controlled, clinical trials of anti-aggressive agents is that their anti-aggressive efficacy is limited to the impulsive, and not the nonimpulsive, aggressive individual. This indicates that psychopharmacology at this time may have little to offer society in the management of criminally motivated aggression. It remains to be seen, however, what the effect of treatment using agents that possibly dampen the function of deeper subcortical structures might be in a group of non-impulsively aggressive individuals. A second potentially important finding is emerging evidence of a differential psychopharmacology in this area so that some subjects may respond to some agents but not others. In our recent studies with fluoxetine, we noted an inverse relationship between pretreatment 5-HT function and anti-aggressive response to fluoxetine. Moreover, most fluoxetine nonresponders appeared to respond to treatment with divalproate, and the latter drug has also been shown to have anti-aggressive activity in selected impulsive aggressive patients with personality disorder. Given, the differential biology of impulsive aggression, it is likely that multiple strategies may be effective in impulsive aggressive individuals, depending on their own individual neurobiological substrate.

Aggressive Behavior: Form and Function

Physiology of Aggressive Behavior

Aggressive Behavior and Stress

Aggressive Behavior and Coping

Glossary

<i>Aggressive behavior</i>	A set of social behaviors closely associated in time with overt fighting.
<i>Defensive aggression</i>	A set of behaviors performed in defense to an attack by a conspecific or a potential predator.
<i>Dominant</i>	The member of a social group that is the winner of the social interactions with all other group members.
<i>Offensive aggression</i>	A set of aggressive behaviors performed against a conspecific aimed to protect resources.
<i>Subordinate</i>	Those members of a social group who lose in interactions with the dominant and never challenge the dominant.
<i>Violence</i>	A form of aggressive behavior which has lost its original biological function and which may cause serious damage to the opponent.

Aggressive Behavior: Form and Function

The existence of different kinds of aggression has long been recognized mainly on the basis of animal research. Two of these, namely instrumental and irritable aggression, are particularly relevant to bridging the gap between human and animal aggressive behavior. Instrumental aggression is a form of aggressive behavior that is instrumentally used to obtain desiderata, whereas irritable aggression is performed in reaction to aversive (social) events. This distinction seems to be analogous to the distinction between offense and defense made on the basis of animal experiments. Offensive behavior is displayed by a dominant resident against an unfamiliar male conspecific intruder of the home territory. Defensive behavior is performed by an animal that is attacked by either a dominant male or a predator. The offense–defense distinction

plays a prominent role in understanding the biology and physiology of animal aggression.

In addition to this distinction between offense and defense, other forms of aggressive behavior can be distinguished as well, such as infanticide, predator aggression, and maternal aggression, which can be observed in females in the late stages of pregnancy and in the early phases of nursing. This article concentrates on intraspecific aggressive behavior in males.

Aggressive behavior has a wide variety of functions depending on the type of aggression. It may serve to protect the home range and its resources against intruders and to maintain the social hierarchy of a group; it may function as a defense against predators, and it can be used instrumentally to obtain desiderata. Overt aggressive behavior such as fighting is usually preceded by an extensive repertoire of introductory threatening behaviors that may be highly ritualized in some species. Aggressive behavior always involves at least two participants, and the interaction usually ends with flight or submission of one of the competitors. Although aggressive behavior is highly functional, it is potentially harmful. Therefore, throughout the animal kingdom, strong reconciliation and appeasement mechanisms have developed to keep aggression in control and to prevent its adverse consequences. From a biological point of view, aggressive behavior is a highly functional form of social communication. However, much of the scientific and public interest in aggression is motivated by the violent, hostile, and presumably less adaptive forms of aggression observed in everyday human life and clinically across a wide spectrum of psychiatric and neurological disorders. The relationship between the functional and maladaptive extremes of the aggression spectrum is still far from clear and forms a major obstacle in the integration of animal research with data on human aggression. For the sake of clarity, the violent aspects of aggression are not discussed.

Physiology of Aggressive Behavior

Aggressive behavior or the threat of aggression is accompanied by strong neuroendocrine and autonomic stress responses in the two participants of the social interaction. The magnitude and the nature of this response depend on the outcome of the aggressive interaction, that is, winning or losing. Because the formation and maintenance of social hierarchies is one of the most important functions of aggressive behavior, much of the stress of everyday life has its

origin in this social structure. The relationship between aggression and stress obviously relates to the physiology of aggression. Therefore, the most important physiological mechanisms underlying aggressive behavior are briefly summarized. A complicating factor is the fact that various forms of aggressive behavior have a different physiological basis. Moreover, the causal physiological mechanisms underlying aggression cannot always be distinguished from the physiological consequences of the aggressive interaction. These consequences are in turn dependent on the outcome of the aggressive interaction, that is, victory or defeat.

Neuroendocrine Factors

Traditionally, high levels of offensive aggressive behavior have been linked to high levels of plasma testosterone. However, the direct causal relationship between testosterone and the expression of offensive behavior is still being discussed. It seems that various kinds of aggressive behavior may be differentially dependent on testosterone, whereas experiential factors strongly interfere with the degree in which aggression depends on plasma testosterone levels. Winning experience results in a temporary increase in plasma testosterone levels, whereas defeat results in a long-lasting decrease. At the level of the brain, testosterone is metabolized into estrogen and dihydrotestosterone. Evidence in rodents shows the existence of separate estrogen-dependent and androgen-dependent neuronal mechanisms of offense.

Due to its high emotional character and the high amount of physical activity, aggression is usually accompanied by a high activation of the pituitary adrenocortical system and the sympathetic adrenomedullary system. However, the reactivity of these neuroendocrine systems appears to differ as an important trait characteristic between highly aggressive and nonaggressive individuals. Aggressive males are characterized by a high reactivity of the sympathetic nervous system and the adrenal medulla, whereas nonaggressive males show a higher reactivity of the pituitary of the adrenocortical axis and the parasympathetic branch of the autonomic nervous system. Recently, hyporesponsiveness of the hypothalamic-pituitary-adrenocortical (HPA) axis has been associated with the development of extreme and presumably pathological levels of aggressive behavior in rats.

Genetic Factors

The role of genetic factors in aggression has long been recognized. Bidirectional selection in rodents usually leads to highly significant differences in aggressive

behavior within three or four generations. Extensive studies in human twins confirm a considerable genetic contribution to the individual level of aggression and violence. The initial studies in humans focused on the XYY syndrome in relation to criminal violence. Several studies in mice addressed the question of to what extent biological variation in aggressive behavior might be due to genetic variation at the Y chromosome. It appeared that the pairing region of the Y chromosome includes the steroid sulfatase gene and the sex-determining region, which might be responsible for at least some of the individual variation in aggression. Behavioral analyses of the rapidly increasing number of genetically manipulated mouse strains show the involvement of more than 50 other genes involved in elevated levels of aggression. Some of these genes code for important components of the neurobiology of aggression such as serotonergic and monoaminergic neurotransmission and gonadal steroid receptors and metabolism. However, for most of these genes it is unknown how they relate to the existing knowledge of the physiology of aggression. Studies aimed at genetic polymorphisms related to individual variation in aggression are mainly performed in humans. So far, the most consistent findings show polymorphism at the promoter regions of the genes coding for the serotonin transporter, for monoamine oxidase A, and for catechol-O-methyltransferase. However, due to the involvement of these neurobiological systems in a wide variety of other behaviors, it is unlikely that this genetic variation is exclusively correlated with aggression per se.

Central nervous organization There is a large body of literature on the central-nervous-system organization of aggressive behavior in animals. The specific involvement of various limbic and midbrain structures depends on the type of aggressive behavior. Offensive aggression involves specific hypothalamic, premamillary, and preoptic areas; the medial and central nuclei of the amygdala; and the prefrontal cortex. Defensive aggression involves the medial hypothalamus, the septal area, and the periaqueductal gray. Evidence suggests that the neuronal systems involved in these types of aggressive behavior are remarkably similar across species and may be homologous to those in humans. High levels of aggression or violence are often associated with functional disturbances in one or more of these brain regions. In the human literature, much attention has been paid to the dyscontrol syndrome, or episodic rage, which is probably attributed to seizure activity in certain brain areas. Brain imaging studies using functional magnetic resonance imaging (fMRI) and positron emission

tomography (PET) in humans with a history of violence and antisocial behavior show a reduced blood flow and glucose utilization in temporal and prefrontal cortical regions.

The most consistent findings of central nervous system functioning in aggressive behavior in both animals and humans, however, involve serotonin (5-HT). Low concentrations of 5-hydroxyindoleacetic acid, a metabolite of serotonin, in the cerebrospinal fluid have been consistently found as a trait characteristic in highly violent, aggressive, or suicidal patients. These findings are supported by many animal studies showing the anti-aggressive effects of selective 5-HT_{1A} or 5-HT_{1B} receptor agonists. Various other neurotransmitters including noradrenalin, dopamine, and γ -aminobutyric acid (GABA) and neuropeptides such as vasopressin are shown to be involved in the control of aggressive behavior in animals as well. However, their role in human aggression and violence is far from clear.

Aggressive Behavior and Stress

An aggressive interaction elicits a strong stress response in both the winner and the loser of the interaction. Evidence shows that winning and losing (or offense and defense) elicits a differential stress response both in terms of the magnitude of responses and of the neuroendocrine stress systems involved. Because winning and losing social interactions form the basis of the social structure in groups of animals, this differential response might underlie the relationship between the position in the social structure and the vulnerability for stress pathology.

Winner

Relatively few studies consider the physiological changes during aggressive behavior in the victor of the social interaction. However, the available literature clearly shows that winning elicits a moderate activation of the HPA axis and of the sympathetic adrenomedullary system. Both human and animal studies also show an activation of the pituitary-gonadal axis in males. More chronically, dominant males in a social group may suffer from sympathetic nervous system-mediated forms of stress pathology. For example, dominant males have a higher incidence of cardiovascular abnormalities such as arteriosclerosis and hypertension, in particular in unstable social groups.

Loser

Most social stress studies concentrate on defense, that is, the loser of a social interaction, or the subordinate

males in a social structure. A comparison of the stress response elicited by various stress procedures reveals that social defeat can be considered as one of the most severe stressors. Both the corticosterone response and the response of epinephrine and norepinephrine are by far the largest during social defeat stress. Recent evidence reveals that stressors show not only quantitative differences but may also differ qualitatively in the pattern of activated physiological systems. For example, a comparison of the electrocardiovascular response to restraint stress and social defeat reveals that the two types of stressors differ strongly in the balance of activation of the two branches of the autonomic nervous system. Social defeat seems to activate exclusively the sympathetic branch, whereas during restraint stress the parasympathetic nervous system shows a considerable activation as well. This differential autonomic balance may explain the high incidence of electrocardiovascular abnormalities observed during social defeat. Social defeat by a male conspecific induces not only strong acute increases in plasma catecholamines, corticosterone, heart rate, blood pressure, body temperature, prolactin, and testosterone but also increases in a variety of central nervous system neurotransmitters including serotonin, norepinephrine, dopamine, and endorphins. There is a general tendency to extrapolate these acute effects observed during and shortly after a defeat to a lasting pathology when the stressor is present chronically, for example, in the subordinate males in a social group. Indeed chronic subordination stress has been reported to induce a downregulation of serotonergic and noradrenergic neurotransmission, lower plasma testosterone levels, and increased activation of the HPA axis. Most of these changes are consistent with the idea that in a variety of animals species subordinates develop depressionlike symptoms. The subordinate position is also related to an increased sensitivity to addictive substances and immunosuppression, resulting in an enhanced vulnerability to infectious disease. Social defeat can be considered as a traumatic life event. Indeed, a single social defeat induces changes in physiology and behavior that can last from days to weeks and months. In fact, many of the behavioral and physiological changes observed after chronic subordination stress can also be observed weeks after a single social defeat.

Aggressive Behavior and Coping

An important concept in aggression research that relates to stress concerns the relationship between aggression and coping. A number of studies in a variety of species shows a strong positive correlation

between the individual level of offensiveness and the tendency to actively cope with any kind of environmental stressor. Aggressive males have a general tendency to actively deal with different kinds of environmental challenges. The antipode of this active problem-focused coping is a reactive or emotion-focused coping style. This is expressed as the absence of aggressive behavior in a social situation and as passivity in other challenging environmental conditions. These coping styles, as observed in several animal species, are also characterized by differential neuroendocrine and neurobiological profiles. They can be considered as important trait characteristics determining the individual adaptive capacity.

Personality factors or trait characteristics have long been recognized as playing a role in human stress psychophysiology as well. For example, the distinction between proactive and reactive coping styles in relation to individual levels of aggression is also made in human beings. The different coping styles as found in animal studies seem to be analogous to the distinction between the human type A and type B personalities used in cardiovascular psychophysiology. The type A personality is described as aggressive, hostile, and competitive and is physiologically characterized by a high sympathetic reactivity. Although the A-B typology has been seriously questioned in the literature, factors related to aggression such as anger and hostility have been repeatedly shown to play a role in the individual capacity of human beings to cope with environmental challenges. Recent studies in feral populations of various animal species show the evolutionary basis of individual variation in aggression and coping or personality as an epigenetic suit of traits.

Individual Differences in Changes of the HPA Axis with
Aging
Conclusion

Glossary

<i>Acrophase</i>	The time of occurrence of the peak, or overall highest values, in recurrent (physiological) cycles.
<i>Circadian rhythm</i>	Roughly 24-h cycle shown by physiological processes in living organisms; from Latin <i>circadian</i> , meaning “around a day.”
<i>Glucocorticoids</i>	A class of steroid hormones characterized by an ability to bind with the cortisol receptor and trigger similar effects;

	the most representative example is the hormone cortisol.
<i>Homeostasis</i>	The ability of a system, especially living organisms, to regulate its internal environment to maintain a stable, constant condition.
<i>Nadir</i>	The time of occurrence of the overall lowest values in recurrent (physiological) cycles.

The Hypothalamic-Pituitary-Adrenocortical (HPA) Axis

The hypothalamic-pituitary-adrenocortical (HPA) axis is one of the most important hormonal systems in the body. It is activated when the homeostasis of the organism is threatened, and is thus commonly referred to as the stress axis. Threats to the homeostasis include physical, pharmacological, and psychosocial stressors. The major components of the axis are both inside and outside of the brain. Upon stimulation, the hypothalamus releases corticotropin-releasing hormone (CRH). CRH is transported to the pituitary gland by way of the hypophyseal portal vessels. In the pituitary gland, CRH triggers the release of adrenocorticotropic hormone (ACTH) into the systemic circulation whereby it is transported to the adrenal cortex and stimulates the synthesis and release of cortisol. These hormones have a variety of effects on the organism, which can be differentiated into permissive, stimulatory, suppressive, and preparative actions. Systems that are sensitive to cortisol presence include immunity, inflammation, metabolism, neural function, behavior, and reproduction. For example, cortisol inhibits the glucose metabolism in non-essential peripheral tissue, while the glucose supply to essential tissues is maintained. Gluconeogenesis and insulin resistance are augmented, while lipolysis, proteolysis, and inflammation are inhibited. Whether cortisol takes stimulatory or suppressive action in the organism depends on the concentration, the time course, and the target area. Cortisol has the ability to cross the blood-brain barrier. Within the central nervous system, it reduces further activity of the HPA axis by occupying mineralocorticoid (MR) and glucocorticoid (GR) receptors in the hippocampus and frontal lobes, which then serve to inhibit subsequent hypothalamus activity and CRH release.

Apart from responding to external stimulation, the activity of the HPA follows a circadian rhythm. The highest levels of cortisol (the acrophase) are usually found in the morning around the time of awakening. Recent studies suggest that awakening might be a stimulus to the HPA axis itself, yielding the highest

levels of cortisol in the first hour after awakening. Cortisol levels then gradually decline until around noon, when a second peak (usually not as high as in the morning) can be observed around lunchtime. During the afternoon and evening, cortisol levels continuously decline, with the lowest levels (the nadir) around midnight. In addition to this circadian rhythm, circavigintan, circatrigintan, and circaannual rhythms of cortisol, reflecting seasonal effects, and menstrual phase influences on HPA axis activity in women have been described. Furthermore, the secretion of cortisol follows a pulsatile pattern, with up to 15 distinct pulses per hour. These constant variations in hormone levels make exact measurement of HPA axis regulation difficult. Special strategies have thus been developed for precise determination, including repeated measurements of cortisol levels with up to 10-min intervals throughout the 24-h period, challenging the HPA axis with pharmacological agents or psychosocial stimuli to assess cortisol reactivity, or assessing activity of the axis at times with high reliability (early in the morning around the acrophase of the axis, or late in the evening when the nadir is approached).

HPA Axis Changes with Normal Aging

Normal aging is accompanied by a number of subtle but consistent changes in the regulation and activity of the HPA axis. In older age, it appears that the amplitude of the circadian rhythm of basal cortisol is reduced, caused by either lower levels in the morning, during the time of the acrophase, or higher levels in the evening, around the time of the nadir. Studies evaluating the stress response in elderly populations concluded that older subjects can still mount a significant endocrine response to a stressful situation, indicating that the psychoendocrine response is maintained into old age. Furthermore, an interaction of aging with gender has been described: while in younger subjects, men usually show the strongest responses to psychosocial stress, recent studies demonstrate that women tend to show stronger responses in older age. For basal levels, it has been reported that women show stronger increases in the morning during the time of the acrophase with aging.

In addition, the feedback sensitivity of the HPA axis is reduced in older age, which might be directly related to the finding of higher basal cortisol levels. It is speculated that with compromised feedback, inhibition of subsequent HPA axis activity is less effective and thus might cause higher cortisol levels. **Figure 1** depicts the global changes associated with normal aging schematically.

Figure 1 Schematic description of age related changes of HPA axis regulation with regard to circadian rhythm (a) and reactivity to stress in young (b) and elderly (c) men and women.

HPA Axis Regulation Changes and the Hippocampus

The hippocampus (HC), an important structure for memory and learning, is implicated in the changes of the regulation of the HPA axis that occur with aging. The HC normally exerts a regulatory function on HPA axis activity through MR and GR receptors, which inhibit the subsequent release of CRH from the hypothalamus.

Since glucocorticoids have been found to be neurotoxic in both rodents and humans, excessive activation of the HPA axis or cumulative activation of the axis throughout the lifetime can damage hippocampal tissue. In animals, it has been shown that hypersecretion of glucocorticoids leads to dendritic atrophy, especially in the CA3 region of the HC. The impaired integrity of the HC is believed to result in decreased inhibition of CRH release from the hypothalamus, and thus a less effective inhibition of subsequent HPA axis activity. This model of impairment that subsequently promotes further damage has been termed the glucocorticoid cascade hypothesis and is one mechanism to explain age-related changes of HPA axis regulation in humans.

Direct evidence for the link between HPA axis regulation and hippocampal integrity in humans stems from recent studies showing that basal cortisol and ACTH levels are inversely associated with hippocampal volume. Earlier, it was shown that acute or chronic increases in cortisol levels either through psychosocial stress or through pharmacological stimulation lead to declined memory performance in cognitive tasks, suggesting that acute or chronic effects of occupation of GR receptors in the HC can impair memory processing in the HC.

Individual Differences in Changes of the HPA Axis with Aging

Recently, evidence emerged for a more dynamic association between changes of the HPA axis regulation and aging. It seems that age-related changes do not occur uniformly, but show significant variation in interaction with other variables. One study uncovered considerable variations in current as well as accumulated cortisol levels and gave clear evidence of subgroups in a healthy aged population. Subjects demonstrated a progressive year-to-year increase in

cortisol levels with currently high cortisol levels, a progressive year-to-year increase in cortisol levels with currently moderate cortisol levels, or a progressive decrease in cortisol levels with currently moderate cortisol levels. Thus, increasing cortisol levels do not appear to be a universal correlate of aging. It seems that age-related changes do not occur uniformly, but may exhibit significant variation in interaction with other variables. This observation prompts the question of whether physical, psychological, or environmental conditions exist when these changes are minimized or augmented. Endocrinologically, recent studies investigating the effects of dehydroepiandrosterone (DHEA) are a good example of the search for variables that potentially modify age-related changes. In the same context, recent studies investigating the effects of estrogen therapy on HPA axis regulation start to show how other hormones interact with aging to affect the regulation of the HPA axis. In genetic research, the identification of risk genes that promote specific age-related diseases, like the APO-E4 gene for the development of Alzheimer's disease, is another good example for this line of research. Similarly, an increasing number of studies investigate the effects of mental illness such as depression or posttraumatic stress disorder on age-related changes on the HPA axis. These studies start to point out the importance of considering lifelong influences on age-related changes in the HPA axis.

Psychologically, it appears that personality variables such as locus of control, self-concept, and self-esteem might contribute to individual differences in age-related changes in humans. These changes were linked to systematic differences in hippocampal volume as well, replicating and extending previous studies showing an interaction between hippocampal volume and HPA axis regulation. Finally, recent efforts to investigate the impact of early-life events (like the quality of parental caretaking) on the HPA axis regulation open a new chapter in HPA axis research, formulating models in which peri- or post-natal variables might program lifelong sensitivity or reactivity variations in HPA axis regulation.

Conclusion

In humans, age is associated with global changes on different levels. The HPA axis is one system that is affected by these changes. In general, it appears that advancing age is associated with a flattening of the circadian rhythm, as indicated by increased basal and

ACTH levels in the evening and decreased levels in the morning. Moreover, it has been shown that the fast feedback inhibition of glucocorticoids on ACTH secretion is reduced with advancing age, suggesting that age might have an impact on HPA axis regulation at different levels. Furthermore, a global age by gender interaction has been reported, with men showing stronger responses to psychosocial stress in young adulthood and women demonstrating stronger responses to stimulation in older age. Unstimulated, there seems to be some evidence that women show stronger increases in the morning during the time of the acrophase with increased age.

In addition to these global changes, recent studies have documented the impact of interindividual differences on age-related changes in the regulation of the HPA. Evidence is now emerging that links age-related changes of HPA axis regulation to variations in personality variables, hippocampal volume, other hormonal systems such as estrogen, and mental illnesses such as depression or posttraumatic stress disorder.

Future studies will have to take into account the effects of behavioral and physiological systems that might exert a lifelong impact on the HPA axis to determine individual changes of the HPA axis with age.

Psychological Stress: Prevalence of Depression and Anxiety
Disorders in Old Age

Determinants of Psychological Stress in Old Age

Consequences of Psychological Stress in Old Age

Conclusion

Glossary

<i>Major depressive disorder</i>	Severe depressed mood and/or loss of interest in activities in combination with additional symptoms such as loss of appetite, sleep disturbance, fatigue, feelings of worthlessness, thoughts about death, or concentration problems.
<i>Generalized anxiety disorder</i>	Chronic, persistent, and excessive feelings of anxiety and worry.
<i>Obsessive compulsive disorder</i>	Repetitive thoughts, images, or impulses that are experienced as intrusive, or repetitive behaviors that are performed in response to an obsession or certain rules.
<i>Panic disorder</i>	Recurring sudden episodes of intense apprehension, palpitations, shortness of breath, or chest pain.
<i>Phobia</i>	Fear and avoidance out of proportion to the danger.
<i>Subthreshold depression</i>	Clinically relevant depressed mood not fulfilling the diagnostic severity criteria for major depressive disorder.

Aging

In the Western world, the oldest of the old, i.e., people aged 85 years and older, comprise the fastest growing segment of the aged. This is due to a decreasing trend in the number of children born as well as to dramatic changes in mortality leading to increased life expectancy. Life expectancy has consistently been higher for women than for men. Consequently, the elderly population is composed of more women than men. So, in absolute terms, aging is affecting women more than men.

Aging has profound consequences for the individual. For the most part, individual aging is associated

with many adverse changes in human anatomy and physiology. Consequences of these changes are, for instance, losses in the sense of balance and movement, poorer hearing and vision, slower reactions, and weaker muscles. For a large part of adult life, people are normally provided with biological reserves. In later life, these reserves are reduced, which can cause a weakening of one or another biological function essential to life. Consequently, conditions such as heart disease, cancer, respiratory infection, and kidney failure may arise. The biological age-related changes and the consequent development of degenerative and chronic conditions, have a large impact on the physical functioning of older people. The number of older people with difficulties in mobility and activities of daily living increases dramatically with increasing age.

In addition to the impact on biological and physical areas, other aspects of life are also affected. Individual aging is accompanied by a series of social transitions, some entered into voluntarily, some imposed by circumstances. In general, aging tends to be associated with relationship losses, either because of retirement, widowhood, or death of age-peers such as siblings or friends. Increasing age also brings changes in relationship needs, for example, as the result of increasing impairment. Older adults may become more dependent on others, when they lose the ability to fulfill certain social or instrumental tasks themselves. The existing balance in their relationships may be disrupted, introducing strain and discomfort.

Most of the age-related changes, biological, physical, or social, can be expected to constitute losses rather than gains. Several of these changes are potentially stressful to older people. Chronic conditions, for instance, can introduce pain, disability, despair, and fear for treatment and pending death. Widowhood, the need for instrumental support, and the loss of personal relationships might cause feelings of loneliness, dependency, and helplessness. When adjustment to these burdening circumstances is inadequate, an older person might experience substantial psychological stress. In the next section, the prevalence of psychological stress in old age is described, indicated by two prevalent affective disorders: depression and anxiety.

Psychological Stress: Prevalence of Depression and Anxiety Disorders in Old Age

Depression

The most prevalent affective disorder in old age is depression. Prevalence rates of depression vary

considerably depending on the sample studied and methods used. Studies in clinical settings generally find much higher prevalences of depression than studies in community settings. Depression can be assessed using either diagnostic criteria or symptom checklists. Diagnostic criteria are described in the *Diagnostic and Statistical Manual of Mental Disorders (DSM)* published by the American Psychiatric Association and are used throughout the world. According to these criteria, a major depressive disorder is present when a total of five or more out of the following nine symptoms are present: depressed mood; lack of interest; feelings of worthlessness or inappropriate guilt; diminished ability to concentrate or make decisions; fatigue; psychomotor agitation or retardation; insomnia or hypersomnia; significant decrease or increase in weight or appetite; and recurrent thoughts of death or suicidal ideation. The identified symptoms should at least include one or both of the two core symptoms (depressed mood and lack of interest), should be present for 2 weeks or more, and should generally be severe enough to cause disruptions in a person's daily functioning. Overall, the symptoms of moderate-to-severe depression presented to the clinician are rather similar across older people and people in midlife. However, there have been described some subtle differences in symptom experience across age groups. Melancholia (symptoms of noninteractiveness) appears to be a little more frequent in later age than in younger age, with psychomotor disturbances being more obvious in older people.

Symptom checklists ask for presence, intensity, or frequency of a series of symptoms during the preceding 1 or 2 weeks in order to measure the extent of depressive symptomatology. Some examples of commonly used symptom checklists are the Center for Epidemiologic Studies–Depression Scale, the Geriatric Depression Scale, and the Zung Depression Scale. These instruments are well validated and have been proven to be valid and reliable instruments in older populations. It is possible to score relatively high on a symptom checklist without meeting diagnostic criteria for major depressive disorder. In fact, depressive symptom checklists identify for the largest part people with a significant high level of depressive symptoms who do not fulfill the diagnostic severity threshold of major depressive disorder. This condition is often referred to as depressed mood or subthreshold depression.

As confirmed in several aging studies, major depressive disorder is relatively rare among older community-dwelling people, affecting only about 1–2% of the community-dwelling population. Major depressive disorder appears to be less prevalent among older adults than among middle-aged adults. **Table 1** shows the prevalence rates of major depressive

Table 1 Prevalence rates for depression in older men and women in different age groups^a

	Age		
	55–65 years	65–75 years	75–85 years

^cIndicated by a score on the Center for Epidemiologic Studies Depression Scale of 16 or more.

disorder in a community-based random sample of older men and women aged 55 years and older who participated in the Longitudinal Aging Study Amsterdam (LASA) in The Netherlands. This table shows that among older people, the prevalence of major depressive disorder shows a slightly declining trend with increasing age. Some have suggested that part of the declining prevalence of major depression with older age could be due to bias since those with depression may die earlier and therefore not survive to old age, or due to the fact that older people may underreport depression compared to younger people. Nevertheless, research findings do indicate that the prevalence of major depression in old age is at least not higher than in earlier age. In addition, it is important to realize that a large proportion of older people with a major depressive disorder have had depressive episodes during earlier phases of their lives. Consequently, a personal history of depressive disorder is one of the strongest risk factors for a major depressive disorder in old age. Thus, major depressive disorders in old age most often represent recurring episodes of early-onset depressive disorders. At all ages, older women generally show a higher rate of major depressive disorder than men.

When using a depressive symptom checklist it becomes obvious that a much higher proportion of the population suffers from significant symptoms of depression. Prevalences of subthreshold depression in older community-based populations are in the range of 12–20%. Data from several community studies converge in suggesting that there is a curvilinear relationship between age and depression scores over the entire adult life span, with the highest scores among younger adults and those aged over 75 years. **Table 1** illustrates the positive association between a

significant level of depressive symptoms and age in older participants of the LASA study. In line with findings for major depressive disorders, women generally show higher rates of significant depressive symptoms than men. The elevation in scores among the very old has been shown not to be an artifact of greater endorsement of somatic symptoms. In sum, the prevalence of minor depression increases across old age, whereas the prevalence of clinical major depression generally does not.

Anxiety

A variety of anxiety disorders are described in the DSM, including (1) panic disorder, which refers to recurring sudden episodes of intense apprehension, palpitations, shortness of breath, and chest pain; (2) phobias, which are fears and avoidance out of proportion to the danger; (3) obsessive–compulsive disorder, consisting of repetitive thoughts, images, or impulses experienced as intrusive or of repetitive behaviors that are performed according to certain rules or in a stereotyped fashion; and (4) generalized anxiety disorder, entailing chronic, persistent, and excessive anxiety and worry. The prevalence of anxiety disorders tends to decline over the lifetime. Nevertheless, anxiety disorders are still common in older adults. Table 2 reports the prevalence rates of various anxiety disorders in the LASA study. In this older population, anxiety disorders are more common among women than men, but are not associated with age. Generalized anxiety disorders are more common than panic disorders and phobic disorders. Obsessive–compulsive disorder was the least prevalent.

Like in younger ages, comorbidity of anxiety disorders is not uncommon in older age. In the LASA study, about 10% of the older people with an anxiety diagnosis suffered from two or more anxiety disorders. Also, anxiety and depression disorders frequently co-occur at any age. Thirty-six percent of the older people with a major depressive disorder had one or more anxiety disorders. Vice versa, 13% of those with an anxiety disorder had a major depressive disorder.

Determinants of Psychological Stress in Old Age

Genetic and Biological Vulnerability

Some research studies have indicated that major depressive disorder and subthreshold depression in older age have distinct underlying etiologies. In general, major depressive disorder appears to be more strongly associated with longstanding vulnerability

Table 2 Prevalence rates for anxiety disorders in older men and women in different age groups^a

Disorder	Age		
	55–65 years	65–75 years	75–85 years
Panic disorder ^b			
Men	0.3%	0%	0.3%

factors such as personality and heredity than subthreshold depressed mood. A large proportion of older people with a major depressive disorder have had depressive episodes during earlier phases of their lives. Consequently, a personal history of depressive disorder is one of the strongest risk factors for a major depressive disorder in old age. Other heritability and personality characteristics, such as a family history of depressive disorder or neuroticism have also been found to be predictive. Also anxiety disorders in late life are often associated with longstanding vulnerability factors such as personality and heredity. Thus, both major depressive disorders and anxiety disorders in old age most often represent recurring episodes of early-onset disorders.

Furthermore, some biological vulnerabilities may predispose an older individual for affective disorders. Age-related physiological and brain structure changes have been suggested as plausible risk factors for late-onset depression because of parallels between these changes and pathological changes observed in depression, such as dysregulation of the monoamine system, increased monoamine oxidase activity, deficits in norepinephrine functioning, downregulation of serotonin receptors, and deep white- and gray-matter disease. Recently, much attention has been directed to vascular risk for late-life depression. Several studies have suggested that vascular lesions in selected regions of the brain may contribute to a unique variety of late-life depression. The vascular depression impairments resemble impairments exhibited

in frontal lobe syndromes. Magnetic resonance imaging of depressed patients has revealed structural abnormalities in areas related to the cortical-striatal-pallidal-thalamus-cortical pathway. Endocrine changes have also been associated with late-life depression. For instance, major depression and panic disorders have been associated with elevated basal cortisol levels, elevated awakening curves of cortisol, and nonsuppression of cortisol, which all suggests hyperactivity of the hypothalamus-pituitary-adrenal (HPA) axis. Although these disturbances have been found among older people as well, there are some recent studies that indicate that physical frailty could actually exhaust the body's responses to stress resulting in hypoactivity of the HPA axis. This may explain why some studies among older frail people have actually observed hypoactivity of the HPA axis among depressed people. For other trauma-related stress disorders (e.g., post-traumatic stress disorders), a higher occurrence of hypoactivity of the HPA-axis has also been confirmed. How other types of anxiety disorders (e.g., social phobia and panic disorders) relate to HPA-axis activity has not been examined in detail yet. Finally, low levels of sex steroid hormones, such as testosterone, estradiol, and dehydroepiandrosterone sulfate (DHEAS), which are especially apparent in older women, have been indicated to result in the development of late-life depressive symptoms and maybe even depressive disorders.

Psychosocial Determinants

Whereas biological vulnerability generally seems to increase with age, in terms of psychological predisposition older adults may be less vulnerable than younger adults. Although stressful life events still appear to increase the risk of depression in old age, the relationship between life events and depression may actually be less strong in older than in younger adults. Older individuals have had the opportunity to learn how to cope with stressful circumstances and how to adjust their expectations so as to have fewer feelings of failure. On the basis of age and experience, older people have developed more effective skills with which to manage stressful life events and to reduce emotional distress. Specific stressors, such as loss of partner or other intimates, are more normative in old age and usual in that part of the lifecycle than in younger age, and therefore probably less disruptive. Although their impact might be smaller than in younger age, social circumstances have still been found to be predictive for depressive as well as anxiety symptomatology. The absence of a partner, a smaller social network size, and lower exchange of emotional support are all important factors that increase the chance of experiencing more feelings of depression

and anxiety in old age. Also, depression and anxiety are more common in older people with unfavorable socioeconomic circumstances, such as low income or education.

Somatic Health Determinants

The importance of physical health for the presence of psychological stress is undisputed. Physical illnesses are consistently shown to be included among the strongest risk factors. For instance, depressive symptomatology appears to be higher in the presence of the following diseases: lung disease, arthritis, cancer, diabetes, stroke and coronary heart disease, and other cardiac illnesses. In addition to specific disease, depressive symptoms are also more prevalent in the presence of certain impairments, such as hearing and vision problems and cognitive impairment. Several explanations can be given for the link between physical health and affective disorders. First, affective disorders can occur as an outcome of certain somatic illnesses or medication, reflecting a biologically mediated process. For example, the structural and neurochemical changes involved in stroke and parkinsonism can lead to depression. Second, physical illness can act as a stressor and has several psychosocial consequences. For example, loss of function, role, and independence, negative body image, and sense of identity, pain, and promoted sense of helplessness can be a reaction of being ill and consequently cause increased feelings of depression or anxiety. Finally, it should be mentioned that physical illnesses and depression or anxiety may exhibit similar symptoms, causing artificially raised correlations. For example, silent myocardial infarctions can produce anxietylike symptoms and some symptoms of depression, especially the somatic symptoms such as the presence of a low energy level and sleeping problems, may partly be a manifestation of the disease. Among older people, it is sometimes rather difficult to distinguish pure emotional consequences of a somatic condition from depression. According to psychiatric criteria, a major depressive disorder is only present when not all the depressive symptoms are clearly the consequence of one somatic condition or the use of a certain pharmacological drug. So, this distinction needs to be considered when evaluating the presence of a depression.

Both the biological age-related changes and the consequent development of chronic conditions and impairments have a large impact on the physical functioning of older people. The extent of physical disability is an important factor in the development of psychological stress.

Several studies among older people have shown that symptoms of depression and anxiety are more strongly predicted by problems with activities of daily

living (disability) than by number of chronic conditions. This illustrates that a disability measure identifies the comorbidity, severity and consequences of chronic conditions better than a simple count of the number of chronic conditions.

As mentioned previously anxiety and major depressive disorders are not more prevalent in old age than in young age. By contrast, subthreshold depressed mood shows an increasing trend with increasing age. Nevertheless, the risk factor profile for subthreshold depressed mood over the lifespan is rather stable in terms of the domains represented. Risk factors in younger people have also been found in old age (e.g., physical health problems, negative life events, and lack of social support). However, the importance of risk factors relative to each other may vary across the lifespan, since the distribution of these risk factors is related to age. For instance, the oldest-old report more social isolation and impoverishment, and have more physical health problems and disability. The relative increases in the prevalence of these risk factors, especially in physical health problems, have been found to completely explain the increased prevalence of subthreshold depressed mood in old age. Thus, what seems to be an association between age and depressive symptoms is in fact the result of other risk factors. Age *per se* is not a risk factor for subthreshold depressed mood when other factors are taken into account.

Consequences of Psychological Stress in Old Age

The presence of psychological stress in old age has several adverse health consequences. These consequences have mainly been studied for depression. Since there has been a striking lack of attention to the health consequences of late-life anxiety, this section will mainly focus on the described adverse health outcomes of depression.

Depressed older people have been found to have a higher overall mortality risk during a subsequent follow-up period than nondepressed older people. These increased mortality risks have been described for older people with major depressive disorders as well as for those with subthreshold depression, although risks were generally smaller for the latter. Although not as consistently as for depression, there are a few recent studies that confirm a similar association for anxiety problems: both assessments of anxiety symptoms as well as anxiety disorders have shown to increase the risk for subsequent overall mortality.

Consistent associations with depression have also been found for various other indicators of somatic health decline. For instance, depression increases the

risk for subsequent onset of physical disabilities in mobility or in activities of daily living. Researchers have further detailed the evidence for health decline associated with depression by documenting increased risk of developing hypertension, stroke, and cardiovascular disease among older depressed people. In addition, there is evidence that high levels of depressive symptoms in cardiovascular patients predict an increased future risk for recurrent myocardial infarction and mortality. However, depression appears to be also associated with noncardiovascular mortality so, although less explored, it is likely that depression may impact mortality through various different, and not exclusively cardiovascular, mechanisms.

It is unclear whether the effect of major depressive disorders or depressive symptoms on physical health decline is different in young and old people. For mortality, a few studies described that the association between depression and mortality is weaker among older people, but other studies did not find a difference between young and old people. For other health outcomes, the possible differentiating effect of age in the association between depression and declining health has not been much examined.

How can the adverse health consequences of depression in older people be explained? First, psychological stressors have physiological accompaniments, including altered autonomic balance, and increased HPA axis function, both of which are biologically plausible contributors to pathogenesis. When anger or depression is induced in laboratory studies, people exhibit larger sympathetic nervous system-mediated cardiovascular responses, as documented by larger increases in daytime urinary epinephrine excretion and downregulation of lymphocyte β -adrenoceptors. There is also evidence that parasympathetic nervous system function is reduced in both anxious and depressed people. In addition, depressed people have been shown to exhibit hypersecretion of the adrenal steroid cortisol, adrenal hypertrophy, and an increased cortisol response to adrenocorticotrophic hormone. The resulting hyperactivity of the HPA-axis could result in activation of inflammatory processes (inflammation). Increased levels of inflammatory markers (e.g., interleukin (IL)-6, tumor necrosis factor (TNF)- α , and C-reactive protein) have been demonstrated among patients with depression. Overall, these physiological processes, especially when persistent in time, could result in elevated resting heart rate and blood pressure, decreased heart rate variability, and increased ventricular arrhythmias and myocardial ischemia, and may explain why depressed older people are more vulnerable for subsequent health deterioration or for onset of some conditions.

Second, increased behavioral risk profiles in depressed people may explain their higher risk for adverse health consequences. Behavioral risk factors appear to cluster in the same individuals. Increased smoking and alcohol consumption are well documented in depression. Depressed people not only smoke more often, they are found to be less likely to quit smoking and might inhale more deeply and smoke more of the cigarette than nondepressed smokers. Also greater 24-hour caloric intake, and cholesterol/high-density lipoprotein cholesterol (HDL/C) ratio have been found. Depressed people engage less in physical activities such as walking, gardening, and vigorous exercise activities such as sports.

Third, related somatic symptoms of depression such as fatigue or sleeplessness may worsen the health status of older people. This explanation is in line with findings that vital exhaustion (which has shared common characteristics with depression such as listlessness, loss of energy, irritability, and sleep problems) increases the risk of developing cardiovascular disease. Another mechanism linking depression to subsequent health deterioration may be via psychological mechanisms. Depressed mood may impede recovery processes by discouraging people from obtaining adequate medical attention and rehabilitation and following treatment regimens.

In summary, depression has several adverse health consequences ranging from increased risks of mortality, decline in physical function, and onset of cardiovascular disease. Subsequent health deterioration can be due to physiological changes induced by depression, the unhealthier behavioral risk profile of depressed older people, the somatic accompaniments of depression, or the decreased motivation of depressed older people for self-care.

Conclusion

This article has described that, although the prevalence of major depressive disorder in old age is rather low, anxiety disorders and significant depressive feelings (minor depression) are common in old age. The prevalence of minor depression increases across older age. Major depressive disorders and anxiety disorders are strongly associated with long-standing vulnerability factors such as personality and heredity, whereas minor depression is more often a reaction to the stressors encountered in later life such as worsened health status, economic stress, and the changing social context. Several adverse health

consequences of depression have been described ranging from mortality, declined physical function, and cardiovascular disease.

Depression and anxiety are potentially modifiable conditions. Unfortunately, appropriate care is often not provided for mental problems in older people. This is partly due to the poor recognition of these problems by physicians. Significant feelings of anxiety or depression in older people more often go unrecognized and untreated than in younger people. Older people are more likely to attribute depressive and anxiety symptoms to physical problems and, therefore, tend to present their problems as somatic complaints, rather than as a psychological problem. Furthermore, the fear of stigmatization in older people may cause underreporting, and bias of clinicians (ageism or age-related prejudice) causes underrecognition of psychopathological disorders in late life. Consequently, recognition, prevention, and treatment are important points for intervention of affective disorders in older people.

Aging and Cellular Stress Resistance
Stress Responses in Intact Organisms

Glossary

Biological aging

The progressive changes that occur during adult life, many of which are deleterious. Aging rate cannot be measured in individuals. For populations, aging rate is estimated by the slope of the line relating the logarithm of mortality rate to age (Gompertz acceleration parameter); it can also be expressed by the mortality rate doubling time (MRDT; closely related to maximum life span) – approximately 8 years for humans and 3 months for laboratory mice. However, in extreme old age in many species, this relationship breaks down.

Epistasis

The canceling of the phenotypic effects of one gene by the expression of another.

Population aging

Time-related changes in the age structure of populations, in which, due to a combination of increased life expectancy and reduced birth rates, the relative and absolute numbers of old people present in many human populations has greatly increased.

Psychological aging

Changes in behavior and mental processes that arise as individuals progress through life.

Senescence

Aging; sometimes used to refer only to those changes that are deleterious. Cellular senescence occurs when a phenotype of cells that are usually capable of mitosis lose the ability to replicate after a number of cycles of cell division but are not dead (Hayflick limit).

Aging *in vivo* is often related to damage done to molecules, cells, and organs by a variety of toxic factors, either produced endogenously or derived from the environment. For our purposes, potentially (or

actually) harmful conditions are considered as stressors and the psychological and biological reactions thereto as the stress response. In the discussion that follows, we address two important issues concerning the relationships between stress and aging: do stressors affect the rate of aging and does aging affect responses to stressors?

Aging and Cellular Stress Resistance

Stressors for cells include the nonenzymatic glycation of proteins and DNA, as well as oxidative damage to diverse molecules that could be caused by free radicals generated mainly as a by-product of metabolism, by solar radiation, by a variety of stressors that elicit the heat shock response, and by numerous other toxic factors in the environment. Normal function, and even survival, is dependent on the ability of cells to sustain homeostasis by being able to adapt to and/or resist stressors, and to repair or replace damaged molecules and organelles.

Oxidative Stress

Oxygen radicals are reactive molecular species produced by the one-electron reduction of oxygen. It is estimated that approximately 4% of the oxygen consumed by mitochondria is converted to the reactive oxygen species (ROS) hydrogen peroxide and superoxide during oxidative phosphorylation. These ROS can be converted by a number of distinct processes to highly reactive hydroxyl radicals, which can damage proteins, lipids, and DNA. Not surprisingly, organisms have important defenses against oxidative stress, including the small molecules uric acid, glutathione, ascorbic acid, and vitamin E. Oxidative stress induces the synthesis of several antioxidant enzymes including superoxide dismutase (SOD), catalase, and glutathione peroxidase. These enzymes protect cells and tissues against oxidative damage by converting ROS to nonreactive species.

What is the importance of defenses against oxidative damage during aging? The continued effectiveness of inducible responses to environmental damage are certainly thought to be major factors in resistance to diseases and even in the rate of aging. Indeed, it has been proposed that a capacity for increased life span is latent within most (if not all) species and might be uncovered by treatments that enhance cellular stress resistance. This is based on the observation that all known laboratory-based strategies that extend organism life span, whether by genetic

intervention or environmental manipulation, are associated with an increased ability to respond to environmental stressors and decreased susceptibility to stress-induced damage.

Systemic Stress Responses and Aging

One of the most exciting concepts relating stress and aging is that the rate of aging is governed by the rate of accumulation of macromolecular damage and, therefore, that processes determining this rate also define life span. Damage accumulates when repair or degradation of damaged molecules cannot keep pace with the rate of damage, which itself is determined by the production of damaging agents (e.g., ROS) and their subsequent detoxification (e.g., by antioxidant enzymes). This idea is well developed in the free-radical theory of aging and its subsequent modifications. The modern oxygen radical theory states that the decline in function and increasing mortality rate associated with aging are due to ROS production and their subsequent reaction with cellular components, causing irreparable damage. Despite considerable interest in this theory, there is virtually no evidence that it explains the natural aging rate. However, we are now developing a more general picture of how cellular stress resistance and aging rates might be related, mainly from studies of model genetic systems (*Saccharomyces cerevisiae*, *Caenorhabditis elegans*, and *Drosophila melanogaster*).

Fungal Systems and Aging

S. cerevisiae divides by asymmetric budding, leaving a mother cell and a smaller daughter cell. The mother cell exhibits limited division potential and consequently, a limited life span. At the end of the yeast life span, the cell becomes granulated and dies. Yeasts provide excellent systems for the dissection of complex biological problems, and aging is no exception. Many genes are now known to influence yeast life span. The first mutations isolated that conferred an increased life span came from a genetic screen for mutations that also conferred stress resistance, in this case to starvation. These mutations clustered in four genes, *UTH1*, *UTH3*, *UTH4*, and *SIR4*.

An important biomarker of aging, observed in species as diverse as primates and nematodes, is the accumulation of damaged mitochondrial DNA (mtDNA). It is thought that the cause of these altered forms is oxygen radical damage. The filamentous fungi *Podospora anserina* and *Neurospora crassa* have provided interesting information on at least one form of aging-related mtDNA mutation. In *Podospora*, aging is associated with the release of a circular DNA molecule (α senDNA) from the cytochrome

oxidase subunit I gene (COI) in the mitochondrial genome. Mutations in the nuclear genes *gr* (*greisea*) or *i viv* result in the repression of the production of this α senDNA. Combinations of these mutations result in indefinite life spans. The *gr* gene has been cloned and encodes a protein homologous to the angiotensin-converting enzyme (ACE)1 transcription factor, known to regulate the superoxide dismutase (*SOD1*) and metallothionein (*CUP1*) genes in budding yeast. Therefore, the alterations in stress-associated transcription factors cause dramatic alterations in the rate of accumulation of aging-associated damage, which correlates with life span.

Caenorhabditis elegans

C. elegans is a small (1.2-mm) soil-dwelling roundworm. It has a 3-day life cycle with four larval stages (L1–L4) before the final molt to the adult form. Most worms are hermaphrodites (XX), although males (X0) do exist at a ratio of approximately 1:500. The hermaphrodites reproduce by self-fertilization and live for approximately 20 days. This organism has proved to be very useful in aging research because single-gene mutations have arisen that both extend life span (*age* mutations) and increase resistance to environmental stressors.

The *age* mutations can bring about an up to three-fold increases in life span, attributable to a smaller acceleration of mortality rate with advancing age. Further, the mutations also induce increased resistance to several stressors: heat, ultraviolet (UV) radiation, oxidation, and heavy metals. Many, but not all, mutations that enhance resistance to such stressors are associated with increased life span, which suggests a direct relationship between longevity and stress resistance.

The epistasis analysis of *age* mutations has established two genetic pathways that determine life span. The cloning of genes in the first pathway, *age-1*, *daf-2*, and *daf-16* has shown that an insulin-like signaling pathway governs both aging and responses to stressors in this species. The *age-1* gene encodes a homolog of the mammalian phosphatidylinositol-3-kinase catalytic subunit (PI3K). The *daf-2* gene encodes a protein that is 35% identical to human insulin receptor and 34% identical to the insulin-like growth factor 1 receptor (IGF-1R). The *daf-16* gene is a Fork head transcription factor.

With the free-radical theory in mind, worms carrying either *age-1* (*bx546*) or *daf-2* (*e1370*) have been assessed for antioxidant enzyme activities, Cu/Zn SOD, and catalase. The net effect of these two enzymes is to prevent the production of the highly reactive hydroxyl radical, which is thought to be

responsible for age-associated damage to proteins, lipids, and nucleic acids. The activities of both of these enzymes are elevated in *age-1* and *daf-2* mutant worms in mid- and late life. This is consistent with the idea that *age* mutations result in resistance to intrinsic oxidative stressors. Worms mutant in *age-1* are certainly resistant to extrinsic oxidative stress, as measured by survival during exposure to hydrogen peroxide (H_2O_2) and the O_2 generator paraquat. These results suggest that the insulin signaling pathway negatively regulates antioxidant enzyme activity and that extended life span results from enhanced antioxidant defenses. This strongly suggests that over expression of antioxidant enzymes is sufficient to confer extended life span.

Oxidative stress is also thought to be one mechanism by which insulin action may be impaired. For example, it has been shown that whole-body glucose uptake (reflecting metabolic clearance rate, MCR) during a euglycemic glucose clamp declines with age in humans. On the basis of parallel increases in plasma superoxide production, red blood cell membrane microviscosity, and oxidation state of glutathione, it was postulated that insulin action is impaired by free-radical production. However, any such hypothesis based purely on correlation studies must be regarded as very tentative.

Drosophila melanogaster

D. melanogaster is an insect that has been widely used in both stress and aging studies. Transgenic *Drosophila* lines containing additional copies of the Cu/ZnSOD and catalase genes have been generated, and most lines that have elevated antioxidant-enzyme levels are also long-lived. This demonstrates the importance of these two enzymes in determining life span. More recent experiments suggest that the expression of MnSOD in neurons alone is sufficient to extend life span.

The transgenic *Drosophila* experimental system has also been used to test the role of molecular chaperones in determining aging rates. In these experiments, it was shown that additional copies of heat shock protein (HSP)-70 could reduce age-specific mortality rates in *Drosophila*. Just how HSP-70 retards aging is unknown, but these findings are consistent with other experiments in both *C. elegans* and *Drosophila* in which animals given a mild thermal stress and allowed to recover go on to develop acquired thermotolerance and exhibit extended life span. In these experiments, HSPs are induced and may be the principal cause of slowed aging.

Drosophila has also been used for studying the effects of multiple genes on stress responses and

aging. Selection has been undertaken for *Drosophila* lines that differ in their levels of stress tolerance, and at least one laboratory has demonstrated that selection for stress-resistance produces lines with increased longevity. In addition, some long-lived *Drosophila* lines, selected for late reproduction, are stress resistant.

The Heat Shock Response

The most extensively studied response to acute stressors is the expression of HSPs. HSPs are the products of a family of highly conserved genes, found from bacteria to mammalian cells, that are rapidly transcribed and translated in cells and tissues exposed to a variety of stressors. Recent studies have provided evidence that in the intact animal even a behavioral or psychological stress can elicit the response. HSP genes are regulated by heat shock transcription factors (HSF), which are themselves sensitive to a variety of stressors. The HSPs facilitate the disassembly and disposal of damaged proteins and the folding, transport, and insertion of newly synthesized proteins into cellular organelles. Thus, they facilitate the removal of damaged structures as well as their replacement.

There is very good evidence that the expression of HSP genes is sufficient to increase resistance to thermal stress (thermotolerance) in many circumstances. Across different species, distinct HSP families are important in thermal tolerance. HSP-104 is responsible for tolerance to several environmental stressors in the yeast *S. cerevisiae*, and inducible HSP-70 confers thermotolerance in *Drosophila* embryos and in a range of cultured mammalian cells. The addition of antibodies to HSP-70 compromises survival after thermal stress in fibroblasts.

Stress Proteins and Aging in Mammals

There is good evidence that stress proteins (e.g., HSPs and antioxidants) directly influence aging. It is also likely that the converse is true – aging seems to influence the extent to which stress proteins are synthesized in response to a variety of stressors. The expression of HSP-70 has been studied in inbred strains of animals at different ages and also in cells cultured to senescence. These studies show that there is a striking reduction in the magnitude of the induced response with both age and senescence.

Considerable specificity has been observed for responses to different stressors. For example, the physical restraint of an animal induces HSP-70 expression selectively in the adrenal cortex and in the media of blood vessels. These responses are dependent on the activation of the hypothalamic-pituitary-adrenal (HPA) axis and the sympathetic

nervous system, respectively. Old rats show a reduced HSP-70 response at both sites. Other work has shown a reduced HSP-70 response in the myocardium of old rats associated with reduced protection from ischemia in the Langendorff isolated-heart model. Interestingly, an HSP response may be selective for the nature of the stressor. For example, the hepatic HSP-70 response of old rats to passive heat stress is attenuated, whereas that to exertional heat stress is not.

HSPs are also important in the cellular actions of glucocorticoids, the archetypical stress hormones. High-affinity intracellular binding of glucocorticoids (e.g., estrogens and gestagens) requires that their receptors be present as a heteromeric complex containing a HSP-90 dimer; other proteins such as HSP-70, p59/HSP-56, and p23 may also be present, although HSP-70 appears to be involved in the assembly of the complex rather than a component of it. This complex also serves to prevent the receptor from homodimerization and binding to chromatin and possibly serves to inhibit its degradation.

Stress Responses in Intact Organisms

There is a diverse literature from which information can be gleaned on how complex body systems respond when an organism is subjected to stressful stimuli, but we have chosen to concentrate mainly on those aspects to which we have contributed directly. Experimental studies show that old rats and mice are dramatically more sensitive than the young to the lethal effects of bacterial lipopolysaccharide (endotoxin). Similarly, old, multiply injured humans experience a very high death rate from injuries of a severity that would cause only sporadic deaths in the young.

Laboratory Studies

It has long been known that old age is a risk factor for developing malignant systemic inflammation during infections and after tissue injury (systemic inflammatory response syndrome, SIRS). However, there have been few systematic studies and consequently little information on aging and the inflammatory response, except for a number of *in vitro* studies on neutrophil function.

Methodological problems obscure firm conclusions, but the majority of *in vitro* studies have reported impaired neutrophil responses to a variety of stimuli. In contrast, other *in vivo* studies suggest that inflammation may be exaggerated or dysregulated. We have shown old rats to be dramatically sensitive to the lethal effects of endotoxins and that

this was associated with early and marked neutrophil infiltration of the lungs and liver. Similarly, in a model of pneumonia in mice, the old animals had much more marked inflammatory infiltrates. Our studies of experimental human cutaneous wound healing also showed greater and prolonged neutrophil infiltration in the old, together with lesser and delayed macrophage infiltration.

Although the endocrine and metabolic consequences of physical injury or experimental infections have not been studied in the context of aging, the responses to the lesser stress of physical restraint have. This study reported a delayed return to baseline corticosterone concentrations in the old rats. It was hypothesized that, because glucocorticoids are toxic to hippocampal neurons and the hippocampus exerts a tonic restraint on activation of the HPA axis, repeated stressful episodes promote hippocampal cell loss, reduce tonic restraint, and predispose to exaggerated HPA axis activation in the old animals.

Endocrine and Metabolic Responses

A characteristic pattern of change in hormone secretion and the flux of metabolites is seen in a stressed animal. Typically, the sympathoadrenal and HPA systems are stimulated, together with the secretion of glucagon and the pituitary hormones growth hormone (GH), prolactin, and vasopressin. In contrast, there is a suppression of adrenal androgen production, and complex changes take place in the hypothalamic-pituitary-gonadal and hypothalamic-pituitary-thyroid axes that lead to lower concentrations of at least some of their end hormones. As regards metabolites, glycogen and fat are broken down so that the concentrations of glucose, lactate, nonesterified fatty acids (NEFA), glycerol, and ketone bodies increase in the plasma.

In muscle the persistence of stressful stimuli cause net protein breakdown, whereas in the liver the synthesis of a set of plasma proteins known as the acute-phase reactants (APR) is induced.

Any effects of stressors is superimposed on a background of normal age-related changes. In brief, there is little change in plasma adrenocorticotrophic hormone (ACTH) or cortisol during aging in humans. The concentration of norepinephrine, which is derived from sympathetic nerve terminals as well as the adrenal medulla, tends to rise whereas that of adrenaline does not. There is decreased secretion of GH, which takes place mainly at night, but probably not of prolactin or glucagon. Aging is accompanied by a decline in the turnover rate of glucose and a small increase in its concentration, reflecting insulin resistance. There is a tendency for the concentrations of

fat metabolites also to increase, but the changes in their turnover rates are more controversial. Protein turnover decreases, as we expect from the decline in lean body mass with age.

Responses to hypoglycemia The effect of aging on the endocrine responses to hypoglycemia has been of considerable interest because of the possibility of hypoglycemic episodes in treated elderly diabetics. Earlier studies, using a standard insulin tolerance test (0.1 U kg^{-1}), mostly showed no difference between old and young people, although there are sporadic findings of decreased cortisol, GH, glucagon, and adrenaline responses and an exaggerated rise in norepinephrine in the elderly.

More controlled experiments with the infusion of insulin have confirmed this lack of consistent change in endocrine responses to hypoglycemia, but have shown a tendency for fewer signs of sympathoadrenal activation (e.g., increased heart rate) in the elderly that is not always reflected in diminished responses of plasma catecholamines. There is no unanimity over their sensitivity to the symptoms of neuroglycopenia.

Responses to psychological stress A variety of procedures have been used to study the effect of age on responses to psychological stress in the laboratory, nearly all of which have shown reduced heart rate responses in the old. A number of authors have measured catecholamines, finding a tendency for the norepinephrine, but not the adrenaline, response to increase with age as well as an increase in baseline values. There have been few studies of HPA responses to psychological stress in the elderly, and these demonstrate no failure to activate the system.

In only one study of the effects of chronic stress do different age groups appear to have been compared directly. Urinary free cortisol excretion has been measured in subjects ages 47–78 whose spouses had life-threatening illnesses. There was a correlation with age only in those who were identified as suffering from severe depressive illness. Others have studied elderly people caring for spouses with Alzheimer-type dementia and compared them with spouses not needing to provide care; the caregiving spouses were classified as high or low stress. Plasma norepinephrine was higher in the high-stress group than the others; there were no differences in plasma adrenaline, cortisol, or the sensitivity or receptor density of lymphocyte β -adrenergic receptors. Although younger subjects were not studied, the results were contrasted with the β -adrenergic downregulation observed in young men experiencing the chronic stress of homelessness. A further study reported a tendency for

higher insulin (but not glucose) concentrations in those caring for demented spouses.

Response to trauma

The general response The acute rises in cortisol and norepinephrine after elective surgery tend to be exaggerated in old people, whereas the opposite is seen for pituitary hormones. During the first few hours after moderate to major surgery, plasma cortisol in elderly patients was either similar to or significantly higher than its value in younger ones. There was no difference in plasma ACTH, whereas the GH response was lower in the elderly. However, in men ages 43–77 undergoing colectomy, there was no correlation between plasma cortisol and age. Cortisol and ACTH concentrations also tended to be higher in old than in young patients after cholecystectomy. After a minor procedure (inguinal herniorrhaphy), too, plasma cortisol was higher in the elderly, whereas there was no difference in the response of norepinephrine, adrenaline, or aldosterone.

Over the next few days after injury, plasma cortisol and, perhaps, norepinephrine tend to decline to normal levels more slowly in the elderly than in the young. After moderate to major surgery, cortisol continues to be higher in the old; no corresponding change in ACTH is detectable. There is also no difference in plasma GH during this period. The rate of 17-ketogenic steroid excretion (a crude index of cortisol production rate) was raised for a longer period after surgery in older patients, even though the absolute values were not different between young and old. In apparently the only study of the effect of aging responses very soon after accidental injury, we found no difference in plasma cortisol among patients ages 17–40, 41–65, and 66–92 with a wide range of injury severities.

Hypothalamic-pituitary-adrenal axis activation after hip fracture We have studied hip-fracture patients, who are often frail and in poor health. Cortisol concentrations remain elevated 2 weeks later (unlike younger people with similar severity injuries). The same was true of the cortisol concentrations after they took dexamethasone overnight (suggesting impaired feedback inhibition by cortisol). These differences persisted when further measurements were made 8 weeks after the injury. Such a prolonged period of raised cortisol concentrations could have deleterious systemic effects.

Most reported cortisol concentrations have been measured in the morning, and comparisons would be invalidated if there were changes in its nychthemeral rhythm. Reliable indices of HPA function can be based on urinary measurements made over a 24-h

period. We found that hip-fracture patients had a higher cortisol production rate and urinary free-cortisol excretion rate than healthy elderly women. The latter index, which is particularly useful because it usually reflects the integrated concentration of free, biologically active cortisol in plasma, rose on average approximately threefold. The cortisol production rate rose proportionately less because the metabolic clearance rate of cortisol was lower in the injured patients, so only a modest rise in production rate was necessary to account for the observed increases in plasma cortisol concentration and free-cortisol excretion.

A puzzling aspect of our studies is that hip-fracture patients did not show an increase in plasma ACTH. In fact, when concentrations were measured at the end of a 2-h baseline period leading up to injection of corticotropin releasing hormone (CRH), decreased values were seen compared with the healthy elderly. The total areas under the cortisol- and ACTH-time curves after the injection of CRH reflected this disparity, with that for cortisol being greater and that for ACTH smaller in the patients, although the incremental areas were both decreased. The correlation between cortisol and ACTH seen in the control subjects was completely lost in the hip-fracture patients, and their apparent sensitization to ACTH was not reflected in the slope of the dose-response curve. Combined with a lack of change in the response to small doses of exogenous ACTH¹⁻²⁴, this suggests the presence of a stimulus acting independently of ACTH. However, it is very difficult to know what such a stimulus might be.

Myocardial infarction There have been two comparisons of responses to acute myocardial infarction

in elderly and younger patients. One study found no difference in plasma cortisol or ACTH, measured over a period of 12 days after the event, between patients ages 65–81 and 33–55; there was also no difference in the response to a standard ACTH stimulation test on the twelfth day. The other study reported similar peak C-reactive protein (CRP) levels in patients younger than 60 and older than 70. This study is valuable because it appears to be the only attempt to compare acute-phase protein concentrations between age groups after a standard insult, although it is well known that an acute-phase response occurs in old patients. Comparability is important to establish because CRP levels have been used to distinguish the effects of aging from those of underlying inflammatory disease.

Stress and AIDS

Stress, Immunity, and Health in HIV Infection

Stress Management for HIV-Infected Individuals

Glossary

<i>Acquired immune deficiency syndrome (AIDS)</i>	A global disease of epic proportions that overwhelmingly affects young people, rendering them unable to defend against common pathogens.
<i>Antibody</i>	A molecule, produced by B lymphocytes in response to an antigen, that has the particular property of combining specifically with the antigen that induces its formation.
<i>Antigen</i>	A molecule that induces the formation of an antibody.
<i>Cytokine</i>	A generic term for soluble molecules that mediate the interactions between cells of the immune system.
<i>Cytotoxicity</i>	The ability to kill cells.
<i>Human immunodeficiency virus (HIV)</i>	The causative agent of AIDS; it is a retrovirus that works by systematically disarming multiple components of the immune system, leaving the infected person susceptible to many of the lethal infections and cancers that encompass AIDS.
<i>Interleukins</i>	A class of molecules involved in signaling between cells of the immune system.
<i>Lymphocytes</i>	A class of immune cells, central to all adaptive immune responses, that specifically recognize individual pathogens, whether they are inside host cells or outside in the tissue fluids or blood. Lymphocytes fall into two basic categories: T lymphocytes (T cells) and B lymphocytes (B cells).
<i>Pathogen</i>	An organism that causes disease.
<i>Phagocytosis</i>	The process by which cells engulf material and enclose it within a vacuole in the cytoplasm.

Proliferation

The clonal expansion of lymphocytes resulting from mitogen or antigen challenge.

T-helper/inducer (CD4) cells

A functional subclass of T cells that can help to generate cytotoxic T cells and that cooperate with B cells in the production of antibodies.

Stress and AIDS

Acquired immune deficiency syndrome (AIDS) is the leading cause of death among men and women ages 15–44 in the United States. Human immunodeficiency virus (HIV) infection can be viewed as a chronic disease whose clinical course is dependent, in part, on an infected individual's ability to maintain optimal cell-mediated immunological control over extant and encountered pathogens. There is mounting evidence linking psychosocial stressors with HIV infection and AIDS. Many psychosocial and behavioral phenomena, including stressful events, stress responses, and distress states, have been associated with impairments in the immune system, which could potentially exacerbate the immunological abnormalities and health consequences observed among HIV-infected individuals. Such associations may be mediated, in part, by stress-related alterations in neuroendocrine functioning (e.g., adrenal hormone regulation), on the one hand, or health behaviors (e.g., substance use, self-care), on the other. Specific immunological components important in contributing to the course of HIV infection have also been shown to be associated with stressors and distress states.

How HIV Infection Affects Immune System Functioning

T-helper/inducer lymphocyte distribution HIV binds with the CD4 receptor, which is most prevalent on a type of T lymphocyte called a T helper/inducer, or CD4, cell. As the infection progresses, there are decrements in CD4 cell counts and impairments in the ability of T lymphocytes to respond to antigenic challenge, opening the door to a wide range of opportunistic infections and cancers. HIV epidemiological and clinical immunology research indicates that precipitous drops in CD4 cell counts, particularly when they fall below 200 cells mm⁻³, are highly predictive of the onset of physical symptoms and general clinical decline. Because CD4 cells are depleted in the

advancing stages of HIV infection, increases in functional aspects of lymphocytes might be important in predicting those HIV-infected individuals (with low CD4 counts) who develop opportunistic infections quickly. Some of these functions include the ability to kill tumors and viruses, a process called cytotoxicity.

Cytotoxic functions One type of psychologically sensitive immune function believed to offer primary protection from replicating HIV, as well as surveillance over other pathogens, is cytotoxicity. High-impact psychosocial stressors such as bereavement, which is quite prevalent among HIV-infected individuals and those who are at risk, appear to be associated with decreases in a specific type of cytotoxicity called natural killer cell cytotoxicity (NKCC). Impairments in NKCC may be especially important during HIV infection because CD4 cells are depleted both quantitatively and qualitatively. Natural killer cells may compensate to some degree for HIV-induced CD4 cell deficiencies. Although other cells such as CD8+ lymphocytes may also perform key cytotoxic functions in HIV+ people, less is known about their associations with psychosocial factors.

Herpesvirus infections Some immune measures may reflect the potential contribution of reputed cofactors of HIV disease progression, including rising antibody titers to herpesviruses such as Epstein-Barr virus (EBV), reflecting viral reactivation. Herpesvirus reactivation may transactivate HIV-infected cells, contributing to increases in HIV viral load. HIV-infected individuals who experience elevated life stressors, distress, depression, an inability to cope with these stressors, and/or a sense of social isolation may be at greater risk for reactivation of specific herpesviruses. Both NKCC and T-cell-mediated cytotoxic functions are generally responsible for keeping these viruses in check. Conversely, stress-associated impairments in cytotoxicity may facilitate herpesvirus reactivation in HIV-infected individuals with subsequent HIV replication and progression to AIDS.

Cytokine dysregulation Maintaining adequate cytotoxic capabilities may depend on retaining T helper cell type 1 (TH1) predominance and production of cytokines, or immunohormones, such as interleukin-2 (IL-2) and IL-12. However, a shift to TH2 predominance and the production of cytokines such as IL-4 and IL-10 occurs in HIV infection. TH1s stimulate both specific (T-cell-associated) and nonspecific (NK-cell-associated) cytotoxicity by producing IL-2 and γ -interferon (γ -IFN). IL-12, a recently discovered cytokine produced by monocytes, may also be important

because of its ability to stimulate NK cells and T cells to release γ -IFN. In addition to affecting cytotoxicity, stressors and distress states have been associated with decrements in other key immune system functions, such as phagocytosis and lymphocyte proliferation, which may also be important in HIV infection.

Stress, Psychoneuroimmunology, and HIV Infection

The field of psychoneuroimmunology (PNI) examines how stressors, stress responses, and distress states relate to the immune system by way of neural and endocrine processes. Our perception of the nature of a stressor and the availability of a coping response to that stressor accompany a series of physiological events leading to specific autonomic, neuroendocrine, and neuropeptide changes. Although neuroendocrine and nervous system mediators of stressor-associated changes in immune system functioning have been identified in humans, most work has occurred outside the HIV arena.

Endocrine-immune interactions Many different neurotransmitters, neurohormones, and neuropeptides within the central nervous system (CNS) have been studied as potential mediators of stressor-induced immunomodulation. Two well-delineated stress response pathways, the hypothalamic-pituitary-adrenal (HPA) axis and the sympathoadrenomedullary (SAM) system, have received the most attention. Elevations in glucocorticoids, a product of the HPA axis, enhance HIV replication, are immunosuppressive, and also accompany affective-disorder and stressful experiences. Once glucocorticoids such as cortisol bind to cytoplasmic receptors on immune cells, the complex travels to the nucleus and binds to DNA sequences that control glucocorticoid-regulated transcription genes for cytokine synthesis. Elevated levels of cortisol are associated with impaired immune-system functioning and accompanying decreases in TH1-like cytokine production. Current PNI research examines how distress- or depression-associated cortisol elevations impact immune function (e.g., NKCC) in HIV-infected individuals and how these changes might relate to disease progression by way of impaired surveillance of latent pathogens such as the herpesviruses.

Elevations in peripheral catecholamines, such as norepinephrine (NE), a product of SAM activation, also depress immune functioning via β -adrenergic receptors on lymphocytes. Sympathetic noradrenergic fibers innervate both the vasculature and parenchymal regions of lymphocytes and associated cells in several lymphoid organs, where NE terminals are generally directed into T-lymphocyte zones. Alterations in electrical activity and NE metabolism in the

hypothalamus occur following injection of antigen or cytokine products of T lymphocytes stimulated *in vitro*, suggesting bidirectional communication between the nervous and immune systems.

Lymphocytes are known to have receptors for many neurohormones including serotonin and cholinergic and β -adrenergic agonists, with most evidence for receptors involving β -adrenergic sites. Administration of β -adrenergic agonists has been associated with decreases in mouse and human NKCC and decreased T-lymphocyte proliferation, and these effects appear to be mediated by increases in intracellular cyclic AMP (cAMP). Patients treated with glucocorticoids show increased β -adrenergic responsiveness due to an increased receptor number and enhanced receptor-adenyl cyclase coupling, evidencing a synergy between SAM and HPA axis-generated stress hormones. *In vivo* human studies involving infusion of adrenergic agents have also shown a decrease in leukocyte number and decreased lymphocyte proliferative response to mitogens following epinephrine administration. These immunomodulatory effects are also most likely mediated by cyclic nucleotide action. In addition, agents that increase lymphocyte cAMP (e.g., isoproterenol and prostaglandin E) can impair lymphocyte proliferation and cytotoxicity, whereas agents that increase lymphocyte cGMP levels (e.g., carbamylcholine) enhance lymphocyte proliferative and cytotoxic abilities.

Stress hormones may have profound effects on monocyte/macrophage cell lines and related cytokines (e.g., IL-1). Such effects could have implications for upstream activities such as antigen processing and presentation to CD4 cells. In addition to catecholamines and corticosteroids, pituitary and adrenal peptide stress hormones, such as met-enkephalin, β -endorphin, and substance P, have been shown to stimulate T-cell cytotoxicity, NKCC, and γ -interferon production as well as macrophage functioning.

Stress, endocrine regulation, and HIV infection The regulation of adrenal hormones may have direct relevance for the pathogenesis of HIV infection. One study found that the ability of HIV to infect nonnal human lymphocytes was enhanced by supplementing the cell culture medium with corticosteroids. Viral susceptibility may be related to the efficacy of lymphocyte or NK cytotoxic abilities, which may be compromised by glucocorticoid secretions during stress. Recent work suggests that HIV-infected people have HPA axis abnormalities, which may increase with the progression of disease, favoring a shift from TH1-like to TH2-like cytokine production. HIV-infected people display elevated resting levels of

cortisol, which are associated with lower CD4 cell counts and decreased NKCC. Cortisol specifically promotes decreased production of TH1-like cytokines such as IL-2 while promoting increased production of TH2-like cytokines such as IL-4 and IL-10. Because cortisol can induce programmed cell death in mature lymphocytes, the HPA axis may also play a role in the progression of HIV infection by facilitating the destruction of viable cells.

Through repeated exposure to multiple stressors, HIV-infected people may become particularly vigilant, physically tense, and sympathetically activated for extended periods of time. Those undergoing chronic sympathetic nervous system arousal with subsequent release of NE from sympathetic nerve terminals may experience health decrements because these endocrines may downregulate the proliferation of naive (uncommitted) T lymphocytes. These cells are already significantly depleted in HIV infection, even after successful antiretroviral treatment. Diminished naive T-lymphocyte proliferation may render HIV-infected people less able to respond to novel pathogens, opening the door to opportunistic infections. In sum, the literature supports the notion that elevated levels of cortisol and catecholamines are associated with impaired immune system functioning. Distress or depression-associated neuroendocrine changes impact immune function (e.g., NKCC) in HIV-infected individuals, and such functional changes might relate directly to HIV disease progression by way of impaired surveillance of latent and novel pathogens, which, once reactivated, can stimulate HIV proliferation.

Stress, Immunity, and Health in HIV Infection

HIV-infected people encounter a large number of major stressors, which, based on the way they perceive them, may result in different emotional responses. These affective responses may relate to altered levels of certain neuroendocrine substances (e.g., cortisol and catecholamines) that have been shown to have depressive effects on lymphocytes. These stress responses may also be accompanied by behaviors (e.g., substance use, unprotected sex, and poor medication adherence) that could have negative implications for the health of HIV-infected people. We now summarize the evidence relating depression and health behaviors to immune function and the evidence relating immune alterations to stress-intervening variables (stressor appraisals, coping responses, and social supports) that may influence physical health status.

Depression and Immunity in HIV Infection

Depression and depressed affect are associated with immunosuppression in healthy individuals. Among HIV-infected people, some studies have found that a depressive state was unrelated to changes in CD4 counts or HIV-related symptoms over 6- and 12-month periods, respectively. Other studies examining immunological and health changes over longer periods found interesting but conflicting results. One found that gay men scoring above the criterion for depression showed a faster rate of decline in CD4 cell counts over a 66-month follow-up period than those scoring below this value. This association was strongest in men who were at the earliest stages of disease. In a separate cohort showing more progressed disease at the time of the depression evaluation, these findings were not evident.

Another study showed that chronically depressed affect (sustained severe depressed mood over a 2-year period) predicted declines in CD4 counts among HIV+ gay men without AIDS as compared to a group of nonchronically depressed men matched on age and CD4 levels. Subsequent work, incorporating more sophisticated statistical procedures and time-dependent covariates (including medication regimen), showed that depression, in combination with elevated stressful life events, does in fact predict a faster rate of disease progression in HIV+ men for up to 9 years. Depressive symptoms among women with HIV have also been shown to predict accelerated rates of CD4 cell decline and HIV-related mortality over a 7-year period. Resolution of major depression is paralleled by increases in NK cell cytotoxicity among HIV+ women. Depressed affect may be associated with an accelerated decline in CD4 counts and a faster rate of clinical disease progression among HIV-infected men and women. This association appears stronger when the potential confounding somatic effects of the disease are controlled by either sampling (excluding progressed subjects), questionnaire refinement (excluding somatically based depression items from the test battery), or statistical controls. Beyond studying the influence of depressive symptoms, it is also important to consider the role of anxiety-related symptoms (e.g., tension and rumination) in the quality of life, immune status, and physical health of HIV-infected individuals.

Health Behaviors and Immunity in HIV Infection

Drug and alcohol use is associated with a wide variety of immunological effects that may have direct health implications for HIV-infected individuals. Alcohol use is related to decreased lymphocyte number and

proliferative responses. Alcoholism and related liver disease is associated with impaired NKCC and decreased NK cell numbers. Evidence suggests that alcohol abuse may amplify the suppressive effects of depression on NKCC. The use of substances ranging from injected drugs to cigarettes has been associated with faster disease progression in HIV-infected people. Thus, it is plausible that substance abuse may contribute to a decline in immunological status and possibly faster disease progression.

Little is known about the direct immunomodulatory effects of different forms of sexual behaviors, but it is plausible that repeated exposure to novel strains of HIV and other sexually transmitted pathogens, such as herpes simplex virus (HSV) and human papillomavirus (HPV), may contribute directly to the development of opportunistic infections (e.g., systemic HSV-2 infections) and cancers (e.g., HPV-associated cervical and anal intraepithelial neoplasias). In addition, exposure to these pathogens may indirectly contribute to accelerated disease course by promoting HIV replication.

Maintaining positive health behaviors such as adequate sleep, nutrition, exercise, and, perhaps most important, adherence to prescribed medications are a central part of managing HIV infection. Triple combination antiretroviral therapy with protease inhibitors offers some hope that viral replication can be slowed more efficiently and with a lower likelihood of resistance or undue side effects than prior antiretroviral regimens. Failure to adhere to the rigid and demanding medication regimens can substantially increase the risk of developing drug-resistant strains of the virus. The resulting treatment philosophy, now more than ever, views HIV infection as a chronic disease in which patient management is critical. Incomplete adherence cannot only compromise the effects of the particular protease inhibitor being used, but can also reduce the efficacy of other related compounds to which cross-resistance has developed. The key is consistent adherence to a demanding medication schedule in the context of an already stressful daily existence. Because depressed affect, substance use, risky sexual behaviors, and poor adherence to HIV medications may all contribute to adverse health outcomes among HIV-infected individuals, it is also important to understand the factors that intervene on these phenomena.

Intervening Variables

The mounting stress of HIV infection may cause infected people to appraise their world as uncontrollable, resulting in their inability to deal with

additional challenges and in a greater likelihood of depression, substance use, risky sexual behaviors, and poor self-care. This sequence is more likely among those with inadequate coping skills and sustained social support losses. Several psychosocial factors, such as perceived loss of control, maladaptive coping strategies, and social isolation, have been related to impaired immune functioning in a wide variety of healthy populations. These processes (and intervention-associated changes in these processes) may be associated with immunological alterations in HIV-infected people. Recently, studies have demonstrated a possible link between these psychosocial processes and the physical course of the infection.

Perceived loss of control Various stressors, especially those viewed as uncontrollable, have been associated with decrements in immune function in healthy people. Some of these are particularly prevalent among HIV-infected people attempting to cope with their illness and include bereavement, the stress of being a caregiver for a loved one with a terminal disease, and divorce or break-up. Among HIV+ men, those with more cumulative stress had faster disease progression over a 9-year period. Some work suggests that stress may affect immune declines in HIV+ people by disrupting sleep.

Coping strategies Coping strategies, such as active coping, active confrontation, “fighting spirit,” and denial, have been related to changes in physical health during HIV-infection. The use of active coping was associated with decreased symptom development in HIV-infected gay men. A “fighting spirit” coping strategy also predicted less symptom development, whereas denial coping predicted a greater number of HIV-related symptoms over a 12-month period. Other coping strategies such as avoidance and denial have also been associated with declines in immune function in HIV+ men. During the stressful period of HIV antibody testing, greater avoidance of distressing AIDS-related thoughts predicts greater anxiety, depression, and confusion as well as lower lymphocyte proliferative responses and NKCC after notification of positive serostatus. Increases in the use of denial during the postnotification period also predict a faster progression to AIDS over a 2-year follow-up period. In another cohort of HIV+ men, greater use of denial predicted faster progression to AIDS over a 7.5-year period. Gay men with AIDS who used a strategy called realistic acceptance showed a shorter survival time than those not endorsing this strategy. Realistic acceptance appears to reflect excessive rumination and focus on HIV-related matters, almost to

the exclusion of many other facets of life. It may be that while denial is maladaptive and predictive of poorer health outcomes, obsessing and ruminating about the disease may also have negative health ramifications. Newer work has produced evidence that greater use of distraction as a coping strategy predicts a slower subsequent course of disease over a 7-year follow-up period. Distraction here reflects an effort to focus on living and pursuing activities that are meaningful rather than denying the existence of the infection or refusing to focus on it excessively. This sort of balance between acceptance and nonrumination has also been identified as a common trait of those who are long-term survivors of HIV infection and AIDS.

Social isolation HIV-infected people face a variety of stressors and challenges that they must continually negotiate in an effort to deal with the potentially overwhelming psychological and physical health consequences of their illness. Stigmatization, alienation from friends and family, increased reliance on medical personnel, social disconnectedness, and gradual deterioration of physical health status and immune functioning may leave these individuals feeling socially isolated. Social resources have been found to buffer the negative physical and psychological effects of major life-threatening events. Low social support availability predicts a faster decline in CD4 counts over a 5-year period among HIV-infected men with hemophilia. Larger social network size and greater informational support provided by that network predict greater survival time in HIV-infected men but only among those with AIDS. Greater perceived social support also predicts a slower progression of disease in initially asymptomatic HIV+ gay men over a 9-year period. It remains to be demonstrated whether actively intervening to increase the quality of HIV-infected people’s social support influences their long-term psychological adjustment, immune functioning, physical health status, and subsequent disease progression.

To summarize, HIV infection is a chronic disease often associated with severe psychosocial and physical stressors, which can potentially overwhelm those infected in a number of domains. The stressors that encompass HIV and AIDS impact the way in which those infected appraise day-to-day situations, choose coping strategies, acquire support, and deal emotionally with stressful events in their lives, which in turn can alter stress hormones as well as influence their ability to engage in healthy behaviors. These processes can then lead to alterations in immune system functioning, which may have repercussions for the development of symptoms and increased HIV viral

Figure 1 Model relating stressors, psychosocial factors, neuroendocrine changes, health behaviors, immune status, and disease in HIV infection. CNS, central nervous system; CD4, T-helper lymphocytes; HIV, human immunodeficiency virus.

load. **Figure 1** displays the interconnectedness of these multiple factors in HIV disease.

Stress Management for HIV-Infected Individuals

Stressors, stress responses, coping strategies, and social resources are related to psychological adjustment, immune system function, and the physical course of HIV infection. Stress-management interventions that modify how individuals process and deal with stressors help to reduce distress and facilitate adjustment and buffer the stressors on the immune system. We now know from randomized clinical trial that HIV+ people assigned to a time-limited group-based stress management intervention show reductions in negative mood, improved coping (e.g., less denial), and greater social support as well as decreases in stress hormones such as cortisol and NE, greater antiviral immune function against herpes viruses, and greater signs of immune system reconstitution. Greater improvements in mood and reductions in stress hormones predicted the greatest gains in immunity, thus providing support for a PNI model in HIV infection.

Some of these gains appear to be brought about by the ability of these interventions to modify stressor appraisals, improve coping strategies, and enhance

social support in HIV-infected people. Psychosocial interventions that provide information, skills, and support to infected people can help normalize neuroendocrine levels and can also facilitate the adoption and maintenance of positive health behaviors, including better adherence to demanding antiretroviral medication protocols. Because interventions may also decrease denial and depressed affect, they may, in turn, decrease negative health behaviors (e.g., substance use and risky sex) that are associated with immune system decrements. The improvements in immune function that have been associated with these psychosocial interventions raises the interesting question of whether stress management can help reconstitute the immune system once antiretroviral agents have contained HIV. Although we are now learning much about how stressors and stress management interventions influence HIV disease in gay men, far less is known about other HIV-infected populations that are growing in numbers (e.g., poor minority women and injection-drug users). Understanding the mechanisms through which stressful experiences and stress management interventions contribute to quality of life and the physical course of HIV infection may help the growing populations of infected people who are attempting to manage this chronic disease.

Risk Factors
Policy Interventions

Glossary

Accident An occurrence related to the operation of an aircraft that causes fatal or serious injury to any person or substantial damage to the aircraft.

Air carriers Commercial air transportation companies that transport people and/or goods;

include both major airlines and commuter airlines.

Incident An adverse event with less serious consequences than an accident.

Human factors A scientific discipline aimed at optimizing the human-machine interface.

Pilot error An act by the pilot that is deemed inappropriate and detrimental to flight safety.

Aviation is a complex system. It includes aircraft, airport facilities, regulations, and operation procedures as well as personnel, such as flight crew, air traffic controllers, aircraft dispatchers, and maintenance workers. Civil aviation can be divided into two groups: commercial flights that transport people and goods to generate revenues and noncommercial flights that are operated by private pilots for pleasure or personal business. Commercial flights are operated by air carriers. Noncommercial flights are usually

called general aviation. Air carriers may include major airlines, commuter airlines, and air taxis. These subgroups of commercial aviation are classified according to aircraft capacities and other variables, and they operate under different regulations. Unless specified otherwise, the term airline in this article refers to major airlines, that is, aircraft operations with 10 or more passenger seats or 7500 payload-pounds of capacity. There are approximately 8200 airline aircraft in the United States, transporting approximately 600 million passengers and 14 million tons of goods each year. An aviation accident is defined as an occurrence associated with the operation of an aircraft that results in fatal or serious injury to any person or aircraft damage requiring major repair or replacement. A serious injury is operationally defined as any injury that requires hospitalization for more than 48 h, that involves a fracture, or that causes severe hemorrhage. Aviation incidents refer to adverse events causing only minor personal injury or minor aircraft damage.

Accident Rates

Aviation is the safest mode of transportation. The rate of deaths per 100 million passenger miles is approximately 0.03 for airlines, compared with 0.9 for motor vehicles and 0.06 for trains. In 2004, air carriers in the United States made a total of 10.8 million

departures and flew a total of 1.8 million hours, with 28 accidents and 14 fatalities. The rate of fatal accidents was 0.19 per 100 000 aircraft departures and 0.011 per 100 000 flight hours. Accident rates for airlines have decreased by 94% in the past four decades and have remained fairly stable since 1980 (Figure 1). General aviation and air taxis have much higher accident rates than airlines; approximately 94% of aviation accidents recorded in the United States involve non-commercial flights. In 2004, the rate of fatal accidents per 100 000 flight hours was 1.20 for general aviation and 0.78 for air taxis, which are 108 times and 71 times, respectively, the rate for airlines.

Stress Model

Aviation safety has been studied from various perspectives. Human factors, which aim to optimize the relationship between people and their activities through engineering, technology, training, and resource management, has played a critical role in aviation safety. Human factor researchers consider aviation to be a system consisting of four elements: hardware, software, liveware, and environment. To maintain aviation safety is to keep the aviation system intact and functioning. The aviation system includes many subsystems. Human factors researchers are especially interested in liveware and its interface with other components of the aviation system. The

Figure 1 Rates of total accidents and fatal accidents per 100 000 flight hours for air carriers, United States, 1965–2004. Data from U.S. Department of Transportation, Bureau of Transportation Statistics.

information processing model that elucidates the psychological mechanisms of decision making has been used by human factors researchers to understand and enhance pilot performance. For instance, studies of pilot error in operating instruments and interpreting instrument readings led to the improved design and display of flight instruments.

Selye considered stress to be a normal phenomenon and the reaction to stressors to be a process of adaptation. Based on Selye's seminal work, Haakonson proposed a simple stress model to explain aviation accident causation, in which safety is the state in which performance ability matches performance demand and accidents result from the imbalance between performance ability and performance demand, particularly when performance demand exceeds performance ability. It is assumed that every pilot has a certain level of performance ability that is susceptible to gradual decline during the course of a flight and that every flight operation involves a certain level of performance demand. Pilots face four types of stressors during flight: environmental (e.g., noise, vibration, and turbulence), physiological (e.g., sleep deprivation and fatigue), emergency (e.g., fuel shortage and engine malfunction), and life events (e.g., financial strain and marital problems). Some of these stressors can be detrimental to performance ability and others can increase the performance demand. The stress model posits that pilot-error accidents are in essence the consequences of inadequate coping or maladaptation to stressors.

The stress model culminated a great deal of research in the field of aviation safety during the 1980s, especially in military aviation. Questionnaires measuring pilot personality and life experience were used in various pilot population groups in order to determine the role of personal life stress in aviation accidents. Studies conducted in pilots who were involved in aviation accidents found that the prevalence of adverse life events, such as financial and interpersonal difficulties, was significantly higher in those culpable than those not culpable for their accidents. The implications of these findings, however, are ambiguous. The retrospectively reported data and quasi-experimental design make it difficult to infer causality between personal life stress and aviation accident. The general consensus is that even if there is a causal relationship between personal life stress and aviation accident, pilot personality and recent life experience contribute only to a small fraction of all aviation accidents. Furthermore, these studies are of limited practical significance because personal attributes such as personality and life events are hardly modifiable. Consequently, researchers have shifted their focus from personal life events to the environmental and occupational stressors pilots

must confront while flying, such as adverse weather, mechanical malfunction, medical emergency, fatigue, aging, and alcohol abuse.

Pilot Error

Pilot error is regarded as the last frontier in aviation safety. Overall, approximately 80% of aviation accidents and 50% of aviation incidents are attributed to pilot error. The role of pilot error in aviation accidents, however, varies greatly with the type of flight operation. Pilot error is a probable cause in approximately 35% of airline accidents, 74% of commuter/air taxi accidents, and 85% of general aviation accidents. The most common pilot error identified in airline accidents is inattentiveness (e.g., failing to see and avoid, and improper preflight planning), which constitutes 26% of all pilot errors. Other major categories of pilot error are flawed decision (e.g., misjudging visibility and weather conditions, and flying aircraft with known defect) and mishandled aircraft kinetics (e.g., failure to recover from a stall or improper response to bounce), each accounting for 22% of all pilot errors. The remaining pilot errors in airline accidents are poor crew interaction (11%), mishandled wind/runway conditions (7%), improper instrument flight rules approach (3%), and other (9%). Although the pattern of pilot error is similar between airline accidents and commuter/air taxi accidents, there is a notable difference between accidents of commercial aviation and general aviation (Table 1). Specifically, mishandled aircraft kinetics is more common in general aviation accidents than in airline and commuter/air taxi accidents. The overrepresentation

Table 1 Type of pilot error in aviation accidents by aviation category (%)

Type of pilot error	Airlines	Commuters/ air taxis	General aviation
Inattentiveness	26	23	25
Flawed decision	22	20	22
Mishandled aircraft kinetics	22	18	38
Mishandled wind/runway conditions	7	18	11
Poor crew interaction	11	10	0
Other	12	11	4
Total	100	100	100

Data from Baker, S. P., Lamb, M. W., Grabowski, J. G., et al. (2001), Characteristics of general aviation crashes involving mature male and female pilots, *Aviation, Space and Environmental Medicine* **72**, 447–452; Li, G., Baker, S. P., Lamb, M. W., et al. (2002), Human factors in aviation crashes involving older pilots, *Aviation, Space and Environmental Medicine* **73**, 134–138; Li, G., Grabowski, J. G., Baker, S. P., et al. (2006), Pilot error in air carrier accidents: does age matter? *Aviation, Space and Environmental Medicine* **77**, 737–741.

of mishandled aircraft kinetics in general aviation accidents is probably due to the fact that general aviation pilots on average are far less trained than commercial pilots.

It is noteworthy that the prevalence of pilot error has decreased markedly in airline accidents, from 46% in the 1980s to 26% in the late 1990s and early 2000s. The use of advanced technologies (e.g., ground proximity warning systems) and implementation of intervention programs (e.g., cockpit resource management) might have contributed to the decline of pilot error in airline accidents. A similar downward trend has not been observed in commuter/air taxi and general aviation accidents.

Risk Factors

Risk factors are personal or environmental characteristics that are associated with an increased probability of accident occurrence. Over the years, researchers have identified several risk factors for aviation accidents. The pilot's health status is one of the characteristics most scrutinized. Early in the 1930s, studies of student pilots indicated that flight performance, measured by certification tests and accident involvement, was inversely associated with the severity of physical defects. Subsequent research linked selected visual problems and cardiovascular disease to increased accident propensity.

Alcohol use is another risk factor that has been studied extensively. Studies in the early 1960s revealed that over one-third of the pilots who were fatally injured in general aviation accidents had positive blood alcohol concentrations (BACs) at the time of death; and among those tested positive, 57% had $\text{BACs} \geq 100 \text{ mg dl}^{-1}$. Following intensive educational intervention and restrictive regulations, alcohol involvement in fatal general aviation accidents decreased to approximately 8%. Since 1985, the United States Federal Aviation Administration has adopted a zero-tolerance policy regarding alcohol-impaired flying. Pilots are prohibited from flying for 8 h after consuming any alcoholic beverage or with a BAC of 40 mg dl^{-1} or greater. Mandatory alcohol testing programs for airline pilots started in 1995. Each year, at least 10% of airline pilots in the United States are randomly selected for alcohol testing. Those who are involved in an accident are required to submit to alcohol testing within 2 h of the accident. Data from the random testing program suggest that the prevalence of alcohol-impaired flying among airline pilots is approximately 0.06%. The odds of accident involvement for airline pilots under the influence of alcohol (i.e., with a $\text{BAC} \geq 40 \text{ mg dl}^{-1}$) is estimated to be 2.6 times the odds for their sober counterparts. In addition to acute alcohol use, chronic drinking

problems, such as a driving-while-intoxicated history, are also found to be associated with a significantly increased risk of aviation accident in both airline pilots and general aviation pilots.

The relationship between pilot age and flight safety has been the subject of intense research and continuing controversy, mainly because of the federal regulation that requires mandatory retirement by their sixtieth birthday for all airline pilots. This policy, commonly known as the Age-60 Rule, was promulgated in 1960 out of concerns about the potential detrimental effects on safety performance of age-related declines in health status and cognitive functions. Experimental studies using flight simulators suggest that age-related declines are mostly limited to domain-independent cognitive functions; among the few domain-dependent measures that are found to decline with advancing age are time-sharing efficiency and the ability to respond to fast-spoken air traffic control commands. These age-related deficits are due to a decreased working memory capacity in older pilots and can be compensated for to a certain degree by flight experience. The fundamental question concerning the controversy of the Age-60 Rule is whether pilots' risk of accident involvement increases as age rises. The results from epidemiological studies aimed at answering this question are contradictory and inconclusive. To determine the effect of aging on accident risk, researchers must confront both conceptual and practical challenges. Theoretically, aging has two divergent effects on safety performance: the risk due to declines in health and cognitive functions and the benefit from increased flight experience and enhanced safety behavior. Because the adverse and beneficial effects take place simultaneously during the process of aging, it is hard to separate one from the other. Research efforts are further compounded by several practical issues, including the lack of a widely accepted measurement of accident risk, the rarity of airline accidents, the healthy-worker effect induced by the rigorous medical certification process, and the truncated work-life span of airline pilots caused by the Age-60 Rule.

Past safety performance is predictive of future performance. Epidemiological studies indicate that pilots who were involved in an aviation accident or incident in the past 3 years were 70% more likely than those without such a history to be involved in an aviation accident within 3 years. Deviant behavior, such as violating aviation regulations, has a greater effect on accident risk than past experience of accident involvement. The risk of accident involvement for pilots with a prior violation record is more than twice that for their counterparts without a violation history.

Fatigue remains to be a safety concern for airline pilots because they often work extended schedules,

night shifts, and across multiple time zones. It is evident that accident risk increases with duty hours. Airline accidents appear to occur disproportionately when pilots are on flight duty for 10 hours or longer. Current regulations in the United States limit flight time for each airline pilot to 30 h week⁻¹ and 1000 h year⁻¹.

Environmental factors, which play a dominant role in airline accidents, can be easily identified. Of all airline accidents, 25% are directly caused by turbulence and 21% by mechanical failure. Bad weather is also strongly associated with pilot error. In fact, instrument meteorological conditions are recognized as the most important risk factor for pilot error.

Policy Interventions

Airline pilots confront a variety of stressors in their work environment. Although aviation safety has improved remarkably in the past 4 decades, airline pilots have much higher job-related mortality than most other occupational groups. The stress model provides a comprehensive conceptual framework for understanding the causation and prevention of aviation accidents. Pilot error, which is a contributing factor in 35% of airline accidents and 85% of general aviation accidents, can be regarded as the result of inadequate coping with endogenous and exogenous stressors. Factors, such as alcohol use, prior violation history, fatigue, and bad weather, influence accident risk either by impairing pilot's performance ability or by increasing performance demand. Policy interventions, including medical standards, zero-tolerance toward alcohol and drug use, flight proficiency requirements, and work-hour rules, have definitely helped to reduce pilot error and aviation accidents. Programs aimed at enhancing pilot performance ability, however, have their limits. Airline accidents are not merely a function of pilot error or individual risk factors. Rather, they are the results of complex interactions of personal factors, aircraft, and the environment in the context of the aviation system. Advances in technology, which have substantially increased the reliability of the aviation system and decreased pilot performance demand, are largely responsible for the remarkable achievement in aviation safety and will further reduce pilot error and airline accidents.

Acknowledgments

The author's work on aviation safety was funded by Grants R01AG13642 and R01AA09963 from the National Institutes of Health and Grant CCR302486 from the Centers for Disease Control and Prevention.

Preparation of this manuscript was supported in part by a fellowship grant from the John Simon Guggenheim Memorial Foundation. The author thanks Dr. Yandong Qiang for technical assistance and Profs. Susan P. Baker and George W. Rebok for helpful comment.

The Death Knell of Nonspecificity
Summary and Conclusions

Glossary

<i>Dishabituation</i>	The facilitation of a habituated stress response following exposure to an intense or a novel stressor.
<i>General adaptation syndrome (GAS)</i>	A syndrome proposed by Selye that consists of the physiological changes experienced by animals, including humans, during prolonged stress; it consists of three distinct phases: the alarm phase, the resistance phase, and the exhaustion phase.
<i>Habituation</i>	The decrease in the amplitude of the stress response after repeated daily exposure to the same stressor.
<i>Sensitization</i>	The enhancement of a nonhabituated stress response by a stressor of high intensity.

Hans Selye and the General Adaptation Syndrome

Hans Selye deserves much of the credit for popularizing the concept of stress in the scientific and medical literature of the twentieth century. Much of the credit also goes to him for the confusion that has resulted in issues relating to the definition of stress and the conceptualization of how stress plays a role in disease

etiology. From the beginning of his career, Selye emphasized a medical model in advancing his views on stress. In his landmark paper published in *Nature* in 1936, Selye first advanced his notion of stress as a “non-specific response of the body to any demand placed upon it.” He was unwavering in promoting this hallmark feature of his definition of stress until his death in the early 1980s.

Selye also advanced the notion of the stress response unfolding in specific stages, which make up the GAS ([Table 1](#)). Upon the exposure of an animal or human to a given stressor, there is a rapid onset alarm phase. The alarm phase is thought to consist of two distinct phases: shock and countershock. The disruptive effects of the stressor are expressed in a dramatic alteration in homeostatic processes, including regulatory processes affecting blood pressure, circulating levels of glucose, electrolyte balance, distribution of blood flow, and membrane permeability. These shock-related responses to the stressor are counteracted in part by the countershock responses of the adrenal cortex, through the release of corticosteroids, and the adrenal medulla, through the release of epinephrine.

If the stressful stimulus persists over a prolonged period of time, the second stage of the GAS, the resistance phase, develops. During the resistance phase, the organism achieves a state of increased adaptation to the untoward effects of the stressor but is more susceptible to the deleterious effects of other homeostatic

Table 1 Stages of the general adaptation syndrome

Stage	Description
Stage 1: Alarm phase	Shock Countershock
Stage 2: Resistance phase	Syntoxic hormones (anti-inflammatory) Catatoxic hormones (pro-inflammatory)
Stage 3: Exhaustion phase	Depletion of adaptation energy Increase in ulceration of the gastrointestinal tract Increased susceptibility to infectious agents Typically ends in death

challenges. In this phase of the GAS, Selye argued, the adrenal cortex plays a key role through a balanced release of syntoxic and catatoxic steroid hormones. Syntoxic glucocorticoid hormones inhibit inflammatory responses, whereas catatoxic hormones promote inflammatory responses to pathogens. Selye was never able to isolate and identify catatoxic adrenal hormones.

At some undefined point, if the stressful stimulus continues and perhaps increases in intensity, the organism enters the third and final stage of the GAS, the phase of exhaustion. Selye suggested that the onset of this third stage is triggered by depletion of adaptation energy stores. This depletion of adaptation energy is attended by enhanced activity of the hypothalamic-pituitary-adrenocortical axis and the onset of pathophysiological changes in the immune system and gastrointestinal tract, resulting ultimately in the death of the organism. Two critical features of stress for many years, gastrointestinal ulcers and increased susceptibility to infectious agents, are reflected in the changes that are thought to accompany the phase of exhaustion. As for adaptation energy, Selye was never able to measure it; he could only infer its depletion when the organism died from lack of it.

Shortcomings of the General Adaptation Syndrome

Not surprisingly, several aspects of Selye's conception of stress and the specific features of the GAS have been the subject of criticism over the years. It is safe to say that Selye's attempts to popularize the concept of stress as it relates to physical and mental health were extremely successful. In contrast, his conceptualization of stress and the details of the GAS have not stood the test of time. We address a few of these issues below.

Selye's definition of stress has been a major source of concern for investigators in this field for many years. His emphasis on the nonspecificity of the stress response has been especially troubling and some have argued that his writings on this subject were contradictory. For example, although Selye emphasized the nonspecificity of the stress response across many different types and intensities of stressors, he did allow room for individual differences in the stress response. Indeed, he was forced to do this to explain the fact that there are many different pathophysiological changes associated with stress. If the stress response were indeed invariant between individuals, there should be only one type of stress-related disorder. However, he addressed this problem by positing that conditioning factors acted to accentuate or inhibit

particular components of the stress response, leading to individual differences in the expression of the deleterious effects of stress. These conditioning factors could be related to genetic, maturational, or environmental influences. Still, he argued that once the effects of these conditioning factors were stripped away, a constellation of nonspecific responses remained. Few if any investigators support this suggestion today.

Selye's work also placed the adrenal cortex at the center of the stress universe. Indeed, an elevation in secretion of steroid hormones from the adrenal cortex became for some a necessary condition for stress to occur. Beginning with the work of John Mason and his colleagues in the 1960s, the centrality of adrenal steroids in the stress response was supplanted by an emphasis on the participation of multiple neural and neuroendocrine pathways in the stress response, with no single system assuming a position of preeminence.

Prior Stress History Affects Future Stress Responses

Work from our laboratory has focused on one area of Selye's GAS that has received little attention. Specifically, we looked at the effects of prior stress history on the pattern of responses to subsequent exposure to a stressor. In this work, we focused our attention on sympathetic-adrenal medullary responses to stress and we measured plasma levels of norepinephrine (NE) and epinephrine (EPI) in laboratory rats. Plasma levels of NE and EPI have been shown to provide an accurate assessment of the activity of the sympathetic nerves and the adrenal medulla, respectively. For all these studies, rats were surgically prepared with indwelling tail artery catheters that permitted remote sampling of blood.

Three types of nonassociative learning have been studied within a framework of quantifying hormonal responses to stressful stimulation: (1) habituation, the decrease in the amplitude of the stress response after repeated exposure to the same stressor; (2) sensitization, the enhancement of a nonhabituated stress response by an intense stressor; and (3) dishabituation, the facilitation of a habituated stress response following exposure to an intense or novel stressor.

Habituation

Chronic intermittent exposure of laboratory rats to a stressor of low or moderate intensity leads to a significant reduction in plasma levels of NE and EPI compared to control animals exposed to the same stressor for the first time. Several different stressors have been

evaluated, including forced swimming, restraint, immobilization, footshock, and exercise. It is important to note that these chronic intermittent stress paradigms provide animals with a high degree of predictability regarding such parameters as type of stressor, stressor intensity, duration of each stress session, and the time of onset of the stressor each day. When provided with this information after several stress sessions, animals are able to activate stress-responsive hormonal systems to the minimum extent necessary to maintain cardiovascular and metabolic homeostasis during each subsequent exposure to the same stressor. This progressive dampening of plasma catecholamine responses to a familiar and highly predictable stressor provides for a significant conservation of energy expenditure.

Sensitization

When animals are exposed to a high-intensity stressor, there are recurring disruptions in cardiovascular and metabolic processes. One such stressor that has been studied is immersion of laboratory rats in water maintained at 18 or 24°C for 15 min per day for 27 consecutive days. When compared to controls exposed to cold swim stress for the first time, animals exposed to chronic intermittent swim stress had significantly greater elevations in plasma levels of NE and EPI. This sensitized response of the sympathetic-adrenal medullary system to chronic intermittent cold swim stress is dependent on stressor intensity. Chronic intermittent swim stress in water maintained at higher temperatures (30°C) results in habituated responses.

Dishabituation

Dishabituation involves an enhancement of the physiological response to a novel stressor in animals exposed repeatedly or continuously to an unrelated stressor. For example, if laboratory rats are exposed to a brief period of footshock stress each day for several weeks, the plasma catecholamine response to footshock gradually decreases over time compared to the response of a naïve control. However, if these same rats are exposed to a novel stressor (e.g., restraint stress), their plasma catecholamine response is amplified compared to the response of naïve controls to restraint stress. Data from our laboratory and the work of others suggest that exposing chronically stressed animals to an unfamiliar stressor presents a much greater challenge to behavioral and physiological homeostasis than the presentation of the same stressor to a naïve control. In this instance, the departure from the expected appears to be the critical

Figure 1 Nonassociative properties of plasma catecholamine responses (expressed as a percentage of control) in rats exposed to chronic intermittent stress. a, Habituation of plasma catecholamine responses of repeatedly stressed rats to a mild stressor compared to first-time stressed controls; b, Sensitization of plasma catecholamine responses of repeatedly stressed rats to an intense stressor compared to first-time stressed controls; c, Dishabituation of plasma catecholamine responses of rats repeatedly exposed to stressor a when presented with a novel stressor b. The plasma catecholamine responses of the a and b controls are presented for comparison. Note that in the same group of animals, the response to a familiar stressor (R_A) may be diminished, whereas the response to a novel stressor (N_B) may be enhanced. AUC, area under the curve; c, first-time stressed controls; C_A , stressor a controls; C_B , stressor b controls; N_B , rats presented with a novel stressor b; R, rats repeatedly stressed; R_A , rats repeatedly exposed to stressor a.

variable in eliciting an enhanced physiological response to stress. Chronically stressed animals live in a moderately stressful but highly predictable environment. The experimenter arrives at approximately the same time each day, the stress session begins at approximately the same time each day, the intensity of the stressor and the duration of the stress session are held constant, and most of the day is free from disturbance. Against this backdrop of consistency, a novel stressor represents an abrupt and at times a dramatic departure from the consistency of the past (Figure 1).

The Death Knell of Nonspecificity

Although the issue of the nonspecificity of stress responses had been discussed by a host of investigators, no study had attempted to compare neuroendocrine response profiles across a range of different stressors. Recently, such a study was conducted and the measures of the stress response included plasma levels of adrenocorticotrophic hormone (ACTH), corticosterone, NE, and EPI, as well as microdialysate levels of NE within the hypothalamic paraventricular nucleus (PVN). The PVN contains cell bodies

Figure 2 Plasma hormone levels during exposure to various stressors in conscious rats. a, epinephrine; b, norepinephrine; c, ACTH. Each bar represents the mean value for the net areas under the curve (AUCs) for that stressor, where the net AUC for each animal was calculated from the baseline AUC subtracted

of neurons that release corticotropin-releasing hormone (CRH) into the pituitary portal system and NE-containing nerve terminals within this nucleus provide a potent stimulatory signal for release of CRH. The acute stressors that were employed in this study included the following: hemorrhage (10 or 25% of estimated blood volume), intravenous insulin (0.1, 1.0, or 3.0 IU/kg), subcutaneous administration of formaldehyde (1 or 4% solution), exposure to a cold environment for 180 min (4°C or -3°C), and immobilization for 120 min.

The results of this study indicated that the neuroendocrine signatures varied dramatically across stressors (Figure 2). In addition, for those stressors that varied in intensity (hemorrhage, insulin, formaldehyde, and cold exposure), some increments in a given neuroendocrine response were greater from one intensity to the next compared to another neuroendocrine response. For example, the ACTH response to a 25% hemorrhage exceeded by five times the plasma ACTH response to a 10% hemorrhage. In contrast, the plasma EPI response to a 25% hemorrhage exceeded by only twice the plasma EPI response to a 10% hemorrhage. Similarly, the plasma ACTH response to a 4% formaldehyde solution was twice that of the response to a 1% solution. However, the plasma EPI response to a 4% formaldehyde solution was four times greater than the response to a 1% solution.

These two categories of findings (e.g., unique neuroendocrine signatures combined with the absence of proportionate increases across all neuroendocrine responses with increases in stressor intensity) are in striking contrast to the predictions associated with Selye's doctrine of nonspecificity. The results of this study are consistent with a primitive form of specificity whereby each stressor provokes a neuroendocrine response pattern that allows, within some limits, for a maximal homeostatic balance to be maintained.

Summary and Conclusions

It has been more than 65 years since Selye published his often-cited paper in the journal *Nature*. The interdisciplinary field of stress research has matured to a significant degree since that time, and thousands of papers on this topic have appeared in the scientific literature. Many of Selye's original concepts of stress have not stood the test of time; improved analytical

from the total AUC. Stressors shown are saline injection, intravenously (SAL IV) or subcutaneously (SAL SC); insulin (INS) 0.3, 1.0, or 3.0 IU/kg; cold exposure at 4°C or -3°C; hemorrhage (HEM) of 10% or 25% of total estimated blood volume; formalin injection (FORM), 1% or 4% solution; and immobilization (IMMO).

techniques and new discoveries in neuroanatomy, neuroendocrinology, and molecular biology have occurred at a remarkable pace. However, it is important to recognize that Selye did establish a connection between stress and disease that continues to occupy basic and clinical researchers in their laboratories and clinics throughout the world.

Introduction

Effects of Alcohol on Stress

Effects of Stress on Alcohol Consumption

Glossary

<i>Anxiolytic</i>	Anxiety or stress reducing.
<i>Stress</i>	The perception of an event as aversive, in that it concerns harm, loss, or threat.
<i>Stressor</i>	An event that elicits stress.

Introduction

Nearly everyone, from clinicians and researchers, to social and problem drinkers, believes that drinking alcohol can reduce stress. Moreover, this effect of alcohol has been suggested as a reason why people begin and maintain their drinking, despite its abuse potential. These two propositions – that alcohol reduces stress, and that people drink in order to obtain this stress reducing effect – were initially formalized by Conger in the mid-1950s in what has become known as the tension reduction hypothesis. Although the term tension has been replaced over the years by terms such as stress or anxiety, Conger's two basic propositions continue to generate a tremendous amount of investigation. Research includes both

field studies and laboratory experimentation and has involved both human and animal subjects.

Effects of Alcohol on Stress

Historically, the term stress has been variously used to describe the stimuli or events that produce a state of anxiety or apprehension, as well as to describe the complex physiological response to an aversive stimulus. Because people respond to the same stimuli in different ways, however, it has been suggested that stress be defined as the appraisal, or interpretation, of an event as signaling harm, loss, or threat. This approach, adopted here, recognizes that an event may be construed as stressful by one individual, but benign by another. The perception of stress is posited to activate a multidimensional response that may involve a wide range of biological responses (e.g., psychophysiological and neurochemical), behaviors (e.g., escape or avoidance behavior), and in the case of humans, subjective awareness of distress. Not surprisingly, studies of the relationship between alcohol and stress have varied dramatically in terms of both the stressors that are used and stress responses that are measured. Such variability likely has contributed to the complex pattern of findings that characterize this research area.

Animal Studies

Conger's original formulation was based on studies using animals, including rats and cats. It is, therefore, not surprising that extensive animal research (most often using rodents) has been conducted testing the alcohol–stress relationship. Typical stressors include a novel environment, food and water deprivation, experimental conflict, in which conflicting motives

and responses are activated, and noxious stimuli (e.g., electric shock administration, exposure to (aversive) bright environments, and placing an intruder into a resident's cage). These studies tend to show alcohol producing an anxiolytic effect, though the relationships are complex.

Data supporting an anxiolytic effect of alcohol appear strongest in studies using experimental-conflict paradigms. These studies begin by training an animal to run down an alley to obtain food reward. Next a shock is administered to punish this approach behavior. The level of conflict is inferred by the suppression of the approach to the food. Typically alcohol ingestion, through its fear-reduction properties, facilitates the approach behavior.

Whether alcohol reduces stress in animals may depend in part on how stress responding is assessed and the dose of alcohol administered. Pohorecky, who has long chronicled progress in this area, concludes that moderate doses of alcohol have modified both anxiety-related behaviors (such as aggression and conflict), and stress-induced neurochemical changes. These latter responses are present in both the brain and in plasma. The former include levels or turnover of norepinephrine (norepinephrine), serotonin, β -endorphins and γ -aminobutyric acid (GABA), while the latter includes catecholamines, corticosterone, testosterone, nonesterified fatty acids, and amino acids. Moderate doses of alcohol consumption also appear to alter stress-induced changes in the functional activity of the hypothalamo-pituitary-adrenocortical axis. These findings suggest neurobiological mechanisms underlying potential anxiolytic effects of moderate (but not high) doses of alcohol.

Human Studies

The effects of alcohol consumption on human stress have proven to be far more complex than originally thought. Although some would argue that the effects are sufficiently unreliable that the notion of alcohol reducing stress should be rejected altogether, most still would conclude that alcohol can reduce stress. The challenge has been to understand the conditions under which the anxiolytic effects of alcohol should be most apparent, and the possible mechanisms underlying this effect.

A number of factors have been examined that may affect the effect of alcohol on stress. These include individual difference factors and situational factors.

Individual difference factors Individual difference factors include gender, personality traits, drinking history, and a family history of alcoholism. Until recently, the vast majority of studies in this area included only male participants. Despite early reports to the contrary, the consensus drawn from the largest

studies that have included both genders is that effects of alcohol on stress seem to be comparable for men and women. These studies have assessed stress using psychophysiological (e.g., heart rate) and self-report measures, and it is possible that other types of measures of emotional response might reveal gender differences. Even when women appeared more responsive than men to a stressor in sober conditions, this gender difference was not altered by alcohol. There is some evidence, however, to suggest that men and women differ in their beliefs about how alcohol consumption affects them. It is, therefore, possible that at low doses of alcohol, men and women may experience different effects, due to nonpharmacological effects of drinking experiences.

Individuals characterized by personality traits such as sensation seeking or impulsivity have been found to be at increased risk for developing alcohol-related problems. Some have suggested that these individuals may derive enhanced anxiolytic effects from alcohol consumption. Presumably, this would increase the reinforcement value of drinking. Although the studies have not been uniform in their conclusions, there is some support for this hypothesis.

Another individual difference factor that has been studied is drinking history. Specifically, some investigations have found that heavier drinkers, due to their development of tolerance, require greater quantities of alcohol than lighter drinkers to obtain the anxiolytic effects of alcohol. These findings converge with the aforementioned animal data to emphasize the importance of dose in determining the effects of alcohol-stress relationship. It may be that the anxiolytic effects of alcohol are restricted to a relatively narrow range of doses.

In contrast to studies that have subjected participants to a single dose of alcohol during one session, there have been studies that permit evaluation of drinkers over extended time periods. During the mid-1960s through the mid-1970s, a number of experiments examined the effects of alcohol use on stress among alcoholic participants. Although these studies often were limited by small sample sizes, they were impressive for their intensive monitoring of participants for weeks at a time. The methodologically strongest studies of this group indicate an association between alcohol consumption and improved emotional states among these alcoholic participants.

The presence of a family history of alcoholism represents an established risk factor for alcoholism. Several experiments have examined young adults with such a family history. Although at this point in their lives these individuals are not problem drinkers, some of these studies have found that offspring of alcoholic fathers nevertheless experience an increased anxiolytic effect of alcohol. These offspring may be

more responsive to a wide range of stimuli while sober, and, therefore, may be especially sensitive to the sedating effects of alcohol. There is some evidence, however, that some of these enhanced anxiolytic findings actually may be due to family history differences on variables other than stress.

Situational factors Situational factors have been proposed that may influence the effects of alcohol on stress. Alcohol is more likely to reduce stress if it is consumed in the presence of pleasantly distracting activity (e.g., drinking at a party or while watching television) than if consumed without distraction. A second factor that has been suggested to moderate the effects of alcohol on stress is the temporal relationship between drinking and the stressor administration. When alcohol is consumed following a stressor (e.g., after a bad day at work) it may be less effective in reducing stress than if intoxication precedes the stress (e.g., drinking just prior to attending a party). While this latter prediction has been supported by laboratory studies, it remains to be seen if such a pattern also holds in the natural environment.

Mechanisms

Investigators have proposed a number of mechanisms underlying the putative anxiolytic effect of alcohol. These include the view that stress reduction is mediated by a direct pharmacologic influence on the nervous system, as well as the notion that stress reduction is mediated by the effects of alcohol on information processing. Both perspectives recognize that the anxiolytic effects of alcohol are potentially reinforcing and can contribute to alcohol use.

Among those who argue that the anxiolytic effect of alcohol results from a direct effect on the nervous system, there has been debate over whether stress reduction is centrally or peripherally mediated. Support for peripheral mediation comes from research showing alcohol to increase peripheral vasoconstriction while dampening heart rate during a stressor administration. Such work suggests that stress reduction could be restricted to those cardiovascular functions mediated primarily by β -adrenergic action. Other studies have not supported the view that the anxiolytic effects of alcohol are primarily a function of β -adrenergic blocking action. Data from a variety of sources instead seem to favor the role of central nervous system functioning in mediating the putative anxiolytic effect of alcohol. More research is needed to better establish the pharmacologic mechanism for stress reduction.

In contrast to theories positing a direct effect of alcohol on stress response systems are models that view an anxiolytic effect to be a result of the pharmacologic effects of alcohol on information processing.

These models propose that, at moderate and heavy doses, alcohol will impair cognitive processing. This cognitive impairment may or may not alleviate stress, depending on one's circumstances. There are several different models that relate to this indirect explanation. One suggests that alcohol's narrowing of perception to immediate cues and reduction of cognitive abstracting capacity restrict attention to the most salient, immediate aspects of experience. Accordingly, the concurrent activity in which an intoxicated person engages helps to determine the effects of alcohol. Intoxication in the presence of concurrent distraction is predicted to attenuate stress responding, whereas, without a neutral or pleasantly distracting activity, intoxication is not predicted to prove anxiolytic.

Other approaches suggest that alcohol serves to disrupt the appraisal or encoding of new information. Depending on the situation, this cognitive impairment may be anxiolytic. For example, alcohol may be more likely to reduce stress if intoxication precedes the stressor, than if it follows a stressor, as in the latter case, the stressful information would already be encoded prior to drinking. It has also been suggested that alcohol may be particularly effective in disrupting the encoding of information in terms of its self-relevance. The inhibition of encoding processes presumably leads to a reduction in performance-based self-evaluation, which in situations where such evaluation is unpleasant, may reduce stress responses, thus increasing the probability of drinking.

Effects of Stress on Alcohol Consumption

Animal Studies

Animal studies of the effects of stress on drinking behavior have used three types of stressors: shock, restraint, and psychological stressors such as isolation and dominance, sleep deprivation, and early weaning and handling. Alcohol ingestion has been measured during the stressor administration, on the day of the stressor, or on the days following the stressor.

Studies using laboratory animals have found that both physical and psychological stressors are associated with an increased tendency to develop a pattern of drug or alcohol use. One explanation for this relationship is that stress increases the reinforcement properties of drugs, perhaps by increasing glucocorticoid secretion, which in turn may enhance the drug-induced release of dopamine.

Across a number of studies, it appears that the probability of alcohol ingestion is especially enhanced following the termination of a stressor. This may be accounted for in part by the ability of alcohol ingestion to replenish endogenous opiate levels that may become depleted during periods of stress. Studies also suggest that a number of factors may affect the

relationship between stress and drinking in animals. Individual differences in preference for alcohol may affect the stress–alcohol interaction, with stress particularly likely to increase subsequent drinking among animals that have low initial preference for alcohol. Another difference that has been observed concerns neonatal experience, with rats that were weaned earlier showing increased alcohol consumption. Genetic factors have also been implicated as moderators of the effects of stress on alcohol ingestion, with various strains of mice ingesting different amounts of alcohol following stress.

Human Studies

In the 1940s, cross-cultural studies led to the proposal that societies that experienced the most stress were also the societies with the highest per capita levels of drinking. To examine whether stress precipitates alcohol consumption in humans, both survey and experimental studies have been conducted.

A number of retrospective studies have examined the relationship between stress and drinking. These studies indicate a modest increase in drinking (as well as a modest increase in heavy drinking) following stress. This effect may be influenced by a host of individual difference factors, including ethnicity, gender, and age.

Prospective studies have accumulated that assess both drinking and stress over specified time periods. These studies generally reveal a tendency for stress levels to correlate with drinking levels. Further, in many instances, individuals appear to drink in order to cope with stress.

In addition to survey research, experiments have been designed to test the causal relationship between stress and drinking. Often these studies first expose participants to some form of stressor (e.g., threat of shock, a stressful social interaction, or false performance feedback). Next, their alcohol intake is assessed while they participate in what is ostensibly a wine or beer taste-rating task. The critical dependent measure, unbeknown to participants, is the quantity of alcohol consumed. Data from these tasks have been inconclusive. Some studies have found clear effects, such that individuals who were stressed consumed more alcohol than their nonstressed counterparts. Other studies have failed to observe this pattern, and in some cases the reverse has been found, with stress leading to a reduction in drinking. As previously noted with respect to animal research, it may be that drinking is especially likely to increase after the stressor has terminated. Another issue that may obfuscate the findings with human participants is the varied approaches to inducing stress. In some cases, for

example, it is unclear just how effective the stressors were. In summary, while laboratory studies have been equivocal, findings from survey research suggest that increases in stress are associated with increased alcohol consumption.

Effects of Stress on Alcohol Consumption

Modifiers of the Stress–Alcohol Interaction

Conclusion

Glossary

Alcohol abuse

The use of alcohol in a manner harmful to the individual and/or others, such as contributing to the failure to fulfill familial or work obligations but not a severe enough problem to meet criteria for alcohol dependence. *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (DSM-IV-TR), makes a distinction between substance abuse and dependence; once the criteria for dependence have been met, a diagnosis of substance abuse is not possible.

Alcohol dependence

According to DSM IV-TR criteria, a failure to control alcohol use despite repeated attempts, continued use despite the knowledge of adverse consequences, and, in general, compulsive use of alcohol. Alcohol dependence may or may not be accompanied by physiological dependence.

Alcoholism

Excessive alcohol use. Although there is no formally accepted definition of alcoholism, the criteria for alcohol dependence are most frequently used by researchers.

Circadian rhythms

Biological rhythms that have a cycle of about 24 h; derived from the Latin *circa diem* “about a day.”

Endorphin compensation hypothesis

A hypothesis that proposes that the use of alcohol following stress is an attempt to compensate for a decrease in the levels of β -endorphin resulting from the termination of the stressor.

Introduction

The effects of alcohol on the mind, brain, and body are as diverse as the effects of stress. However conceptualized, stress is consistently associated with psychological manifestations, including anxiety, irritability and anger, sad and depressed moods, tension, fatigue, and with certain bodily manifestations, including perspiration, blushing or blanching of the face, increased heart rate, decreased blood pressure, and intestinal cramps and discomfort. Sleep duration and quality are also severely impaired by stress. In the field of substance addiction, both acute and chronic alcohol intake have a disruptive effect on a variety of stressors, both at physiological and psychosocial levels. Three fundamental issues arise: (1) the consequences of stress on normal subjects and alcoholics are not uniform, and the psychopathological and physiopathological impact of stress may be significantly greater in some people than in others; (2) the impact of stress is dynamic and multifaceted, such that the same person may exhibit a variety of manifestations of the psychoneuroendocrine-immune stress response with varying degrees of severity in different situations; and (3) the outcome of stress can be variable in the sense that normal subjects and alcohol abusers may position themselves along the spectrum of allostatic regulation, somewhere between the allostatic state (i.e., toward regaining physiological balance) and allostatic overload (i.e., toward physiological collapse, with associated potential onset of varied pathologies). In brief, subjects with different levels of chronic stress (i.e., major life events or minor hassles) may be expected to respond dramatically differently. Finally, inherited changes in response to alcohol, such as an increase in the ability of alcohol to lessen the impact of stressful events, may themselves confer susceptibility to alcohol abuse. Our understanding of the relationships between alcohol

and stress is based on different lines of research both on animal and human subjects.

Alcohol and the Stress Response

Alcohol and the Neuroendocrine-Immune Response to Stress

Acute alcohol administration has a stimulatory action on the hypothalamic-pituitary-adrenal (HPA) axis and related brain systems in humans and rodents, that is, the brain and pituitary β -endorphin (β -EP) systems and the sympathetic nervous system. Alcohol-induced neuroendocrine effects are characterized by dose-dependent elevations in plasma glucocorticoids, adrenocorticotrophic hormone (ACTH), β -EP, and catecholamines. Ethanol activation of the HPA axis is abolished by hypophysectomy or treatment with corticotropin-releasing hormone (CRH) antiserum in rodents, suggesting that it is primarily modulated by ACTH secretion and that CRH is an essential intermediate in the stimulation of ACTH by ethanol. Acute ethanol exposure generally activates the HPA axis when blood alcohol concentrations (BACs) exceed intoxicating levels of 100 mg dl⁻¹, although HPA activation can also occur at lower BACs. In contrast, the ethanol-induced HPA response of some individuals may be either unaffected or blunted. There are also contributions from environmental and genetic factors to this variability.

Chronic exposure to ethanol has a more variable effect on the HPA axis and the β -EP system, ranging from stimulation to either response attenuation or tolerance. For example, a small percentage of alcoholic individuals (<5%) develop clinical features of hypercortisolism or Cushing's syndrome. However, animal studies suggest that chronic ethanol exposure can result in tolerance to the stimulatory effect of ethanol on CRH release in vitro and can impair the ability of the HPA axis to respond to stress. Indeed, alcoholic men have been reported to show blunted ACTH and cortisol responses to CRH and ACTH challenges, as well as other signs of HPA axis dysfunction (i.e., impaired feedback regulation).

Alcohol consumption acts on the autonomic nervous system as well as the neuroendocrine system, in particular the HPA axis. The latter plays a pivotal role in regulating immune surveillance mechanisms, including the production of cytokines that control the inflammatory process as well as events responsible for healing. Given the multidirectional communication among the neuroendocrine, immune, and nervous systems, alcohol can be expected to impact all three interacting systems, in both feed-forward and feedback directions.

Alcohol and the Cardiovascular Response to Stress

The impact of alcohol on cardiovascular responses varies with the state of the subject at the time of alcohol exposure (i.e., baseline or post-stress) and with the cardiovascular measures employed. Although alcohol has been shown to increase resting heart rate, it also is known to produce a paradoxical decrease in blood pressure in both humans and animals. Thus, alcohol's effect on heart rate is comparable to that of stress, whereas its impact on blood pressure is inconsistent. Heart rate, as a psychophysiological measure of the stress response, has provided evidence for the general assumption that alcohol is often used as a means of relief from the physical and psychological effects of stress. However, human research designed to assess the stress-response-dampening model of alcohol use has had mixed results. There is some indication that contradictions in experimental findings may be due to varying alcohol doses, differences in the subjects employed, and differences in the timing of the stress exposure and the alcohol presentation. Making the issue even more complex is the evidence indicating that altered responses to alcohol may have a genetic basis, possibly even conferring susceptibility to alcohol abuse on those with a family history of such substance-abuse problems. Studies failing to see a stress-response dampening effect of alcohol have often employed rather low doses, providing a logical explanation for differing results; it has also been established that alcohol increases baseline levels of physiological arousal. Thus, when looking at the effects of alcohol on the response to a given stressor and calculating change from baseline, results will differ depending on whether the baseline used is a pre- or postethanol measurement.

Effects of Stress on Alcohol Consumption

Stress and Alcohol Use

Animal studies indicate that stress increases alcohol consumption when the stress, whether physical or social, is chronic, unavoidable, and uncontrollable. Evidence from human and animal studies indicates that alcohol has profound anxiolytic effects. In rodents, tolerance to the anxiolytic effects of low or moderate doses of ethanol was shown to develop rapidly and, as such, may explain the augmented consumption of alcohol required to maintain its tension-reducing effects. In addition, adverse experiences early in life, such as maternal separation, have been found to be associated with excessive alcohol consumption in monkeys as well as in humans. Furthermore, prenatal factors, such as maternal stress and drugs or alcohol consumption during pregnancy,

can dysregulate physiological and behavioral stress responses in adulthood. Such findings suggest that early life experiences can result in long-lasting psychobiological changes that may manifest as enhanced alcohol consumption in order to achieve tension reduction.

Consistent with the stress-response dampening model, it is a common and long-held assumption that alcohol is often used as a means of coping with stress. Recently, however, with the observation that alcohol may or may not dampen physiological responses to stress, new theories have evolved. One that is consistent with many observations and the effectiveness of new pharmacological treatments for alcoholism is the endorphin compensation hypothesis. This hypothesis proposes that alcohol is consumed following the termination of stress because the presence of stress increases levels of the endogenous opioid β -EP. Alcohol is sought for its ability to increase β -EP levels and compensate for the deficit that results when the stress has been removed. Consistent with this hypothesis is the use of naltrexone, an opiate antagonist, in the treatment of alcoholism.

Sleep and Alcohol Use

Sleep disturbance is a common complaint of alcohol-dependent patients. Various studies have demonstrated a strong association between poor sleep and psychological factors, especially in relation to perceived stress and associated increases in CRH and cortisol, the hypothalamic and adrenal products of the HPA axis. Both hormones are known to lead to arousal and sleeplessness in human subjects and experimental animals.

The daily sleep-wakefulness cycle is synchronous with circadian patterns of body temperature in humans and animals such that maximum body temperatures occur during the active portion of each day and minimum body temperatures occur during the inactive or sleep portion. In rodents, the daily active period corresponds with the dark phase of the daily light-dark cycle while sleep occurs during the light phase. Acute administration of ethanol was found to alter the rodent's circadian body temperature and activity rhythms in a dose- and time-dependent manner. Chronic exposure to ethanol has also been shown to alter the amplitude of the rat's circadian body temperature and activity rhythms. Confirmation of these findings in translational studies on human subjects could provide a further basis for alcohol-induced sleep disturbances.

Trauma and Alcohol Use

Despite the controversy as to whether or not alcohol is used to minimize the impact of stress or to

compensate for some post-stress condition, there is an abundance of correlational data linking increases in alcohol use with exposure to or the experience of traumatic or uncontrollable stressful events. For example, studies have demonstrated that there is an increase in social indices of alcohol use (such as arrests for driving while intoxicated) following disasters.

Not only are changes in a population's alcohol consumption associated with traumatic events that affect a community (e.g., natural disasters), but a high percentage of those seeking treatment for alcoholism are survivors of abuse or suffering from post-traumatic stress disorder or other anxiety disorders. Although it may be difficult to determine a direct relationship between victimization and alcohol misuse, attempts to define whether or not alcohol abuse preceded, coincided with, or followed trauma have consistently found that trauma did, in fact, precede alcohol misuse. Furthermore, trauma severity is positively correlated with alcohol consumption and the severity of alcohol-related problems. There is reason to believe that, whereas stress plays a role in the etiology of all drug dependence, the drug selected by men is more likely to be alcohol. Thus, there appears to be a gender difference in the drug of choice for the individual struggling with the aftermath or presence of stressful life conditions.

Traumatic Brain Injury and Alcohol Use

Traumatic brain injury (TBI) and its sequelae are of pivotal importance in the young generation (e.g., in victims of car accidents and in deployed soldiers and war veterans) with consequences ranging from physical disabilities to long-term behavioral and social deficits. Close to 25% of TBI cases are associated with alcohol abuse, and alcoholism may, in and of itself, complicate long-term TBI recovery. A growing body of evidence raises the possibility that alcohol intoxication or dependence in combination with TBI may lead to increased deleterious effects on cognitive functioning. Moreover, serious alterations in neuroendocrine and immune regulation have been noted following chronic alcohol use and TBI in animal models and humans that can impair recovery and rehabilitation efforts after brain injury. However, the role of alcohol as an interactive or additive agent in these findings has not been fully assessed.

Alcoholism, Stress, and Relapse

Stressful life events have long been thought to play a role in the return to alcohol use following cessation of problematic drinking behavior. The role of stress in relapse has received much attention, with more recent

reviews concluding that less severe psychosocial stress may not increase the likelihood of relapse, whereas severe acute stressors and chronic stressors perceived as highly threatening may contribute to an increased risk of relapse. In considering the role of stress in relapse, however, the capabilities of the individual must be considered. The impact of even severe stress and whether this leads to relapse are mediated by both protective and risk factors that render the individual more or less likely to return to problematic alcohol use. Risk factors that may increase the likelihood of relapse to substance abuse include the persisting physiological symptoms of abstinence (e.g., HPA axis dysfunction, characterized by a blunted ACTH response to a challenge with CRH).

The role of stress has been the focus of many alcoholism treatments. Most notably, the relapse prevention model introduced by Marlatt and George in 1984 proposes that the goal of treatment for addictive behaviors must be to develop the means for coping with stressful situations. In order to change addictive patterns, situations that are high-risk for relapse need to be identified and methods for coping with such situations developed. According to the model, cessation of addictive behavioral patterns can be achieved through the mastery of handling such high-risk situations. The relapse prevention model has been the focus of much research, although empirical support for its effectiveness is difficult to obtain. Despite research suggesting that relapse does occur in situations identified as being high-risk, the subjective nature of such retrospective reports calls any definitive conclusions into question.

Modifiers of the Stress–Alcohol Interaction

Genetics

Various inbred murine and rodent strains differ in their sensitivities to alcohol at the endocrine and behavioral levels. In the past 2 decades, with the application of selective breeding techniques, rodent models of alcoholism have been derived with high and low oral alcohol preference. Such animal models are particularly useful in the identification of genetic traits associated with the physiological and behavioral bases of alcohol drinking. For example, results indicate that the β -EP system of alcohol-preferring rats is hyperresponsive to alcohol. Thus, the activation of the endogenous opioid system may either enhance the reinforcing effects of low-dose alcohol or attenuate the aversive effects of high-dose alcohol and thereby affect alcohol consumption,

consistent with the previously noted endorphin compensation hypothesis.

The genetic basis for susceptibility to alcohol abuse and dependence has long been accepted, and numerous studies have been conducted to determine how those with a family history of alcoholism (family history positive, FHP) might differ from those without such an inherited risk (family history negative, FHN). There is increasing support that altered neuroendocrine responses to alcohol in the sons of alcoholic men provide a possible basis for the genetic component in the development of alcoholism. For example, nonalcoholic male offspring of alcoholic fathers (known to be at three- or fourfold higher risk for alcoholism than sons of nonalcoholics) demonstrate, in comparison to the sons of non-alcoholics, lower cortisol responses to alcohol, an impaired ACTH response to CRH, increased alcohol-induced plasma β -EP levels, and an enhanced ACTH response to the opioid receptor antagonist, naloxone. These findings indicate that FHP men have altered hypothalamic CRH neuronal activity. Although it is not clear how these alterations may contribute to the development of abusive patterns of alcohol use, these studies suggest that the CRH-mediated response of the HPA axis or the β -EP system to alcohol may serve as a marker to distinguish individuals at risk for alcoholism. Interestingly, these markers do not effectively distinguish FHP women, supporting the notion that there are gender differences in the role of genetic factors in the etiology of alcoholism.

Expectancy

Adding an additional level of complexity to the determination of the effects of alcohol on the human stress response is the vast literature demonstrating that expectancies have a significant impact on the response to alcohol ingestion. It may be that many reported differences in the literature are created by the influence of cognition on reactivity to alcohol and are due to the timing of stress presentation with respect to alcohol use. Indeed, it appears that intoxication prior to stress exposure may alter the cognitive reaction to the stimulus and, as a result, the response to the stressful stimulus may be minimized. Thus, it may be that alcohol does not merely dampen the stress response but that alcohol may also act to reduce the physiological response to a stressor by altering the appraisal of the stressful stimulus. Such a conclusion is supported by studies that find that more complex paradigms are more likely to result in alcohol stress-response dampening.

Conclusion

There is clearly a relationship between alcohol and stress, although the nature of this association is complex and not easily described. A brief look at the relevant literature demonstrates that the interaction of alcohol and stress varies with characteristics of the subject studied, the environment, the alcohol dose, the nature of the stressor imposed, and the timing of the exposure to alcohol and the stressor. Thus, stress, alcohol, and alcoholism are interrelated, but the nature of this relationship is highly variable. The ineffectiveness of many strategies for prevention and treatment of alcohol abuse and the variation in clinical history represent a challenge and an opportunity to better understand the relationship between alcohol and stress.

Aldosterone: A Stress Hormone?

MR Activation and Stress

Glossary

<i>Aldosterone</i>	The classic salt-retaining steroid hormone secreted from the zona glomerulosa of the adrenal cortex.
<i>Aldosterone synthase/ CYP11B2</i>	The enzyme abundantly expressed in adrenal zona glomerulosa and reported in PCR studies on heart, blood vessels, and brain, which, by a sequential three-step process, converts the methyl (-CH ₃) group at carbon 18 to an aldehyde (-CHO) group.
<i>Apparent mineralocorticoid excess (AME)</i>	An autosomal recessive syndrome of inactivating mutations in the gene coding for 11 β -hydroxysteroid dehydrogenase type 2, producing juvenile hypertension, marked salt retention reflecting inappropriate cortisol activation of epithelial mineralocorticoid receptors, and premature death.
<i>Carbenoxolone</i>	The hemisuccinate of glycyrrhetic acid, previously used as a treatment for peptic ulcer.
<i>Glycyrrhetic acid</i>	The active principle of licorice, which can block 11 β -hydroxysteroid dehydrogenase, leading to sodium retention and blood pressure elevation.

*11 β -Hydroxysteroid
dehydrogenase
type
2 (11 β HSD2)*

*Mineralocorticoid
receptors
(MR)*

The enzyme expressed in very high abundance (3–4 million copies per cell) in epithelial aldosterone target cells that converts cortisol and corticosterone (which have affinity for mineralocorticoid receptors similar to that of aldosterone) to receptor-inactive metabolites, and NAD to NADH, thus allowing aldosterone to activate the relatively non-selective mineralocorticoid receptors.

The intracellular receptors that have equal high affinity for aldosterone, corticosterone, and cortisol and via which aldosterone acts in epithelial tissues to promote unidirectional transepithelial sodium transport.

Background

Classically, aldosterone is the physiological mineralocorticoid hormone uniquely secreted from the zona glomerulosa of the adrenal cortex, and acting via intracellular mineralocorticoid receptors in epithelial target tissues to promote unidirectional transepithelial sodium transport. While this remains the case, over the past decade there has been mounting evidence for additional complexity in terms of aldosterone secretion and action, and of MR activation by glucocorticoids. For aldosterone, this ranges from extra-adrenal aldosterone synthesis, to major pathophysiological actions via nonepithelial mineralocorticoid receptors, to rapid nongenomic actions via a range of receptor mechanisms. There remain major residual areas of ignorance in terms of mechanism. The first aldosterone-induced protein was identified in 1999, a serine-threonine kinase (sgk) that directly or indirectly activates epithelial sodium channels. The mechanism of SGK action, and potential roles for other aldosterone-induced proteins in both epithelial and nonepithelial tissue, remain to be established.

Aldosterone Secretion: Adrenal and Extra-adrenal

Aldosterone was isolated in 1953. It was initially called electrocortin, reflecting its effects on electrolyte transport, but was given the definitive name of aldosterone in recognition of its unique aldehyde (-CHO) group at carbon 18, in contrast with the methyl group in other steroids. Formation of this aldehyde group, which is crucial for the ability of aldosterone to access

mineralocorticoid receptors in epithelia (*vide infra*), is achieved by a three-step process catalyzed by the enzyme aldosterone synthase (CYP11B2), expression of which in the adrenal cortex is confined to the outermost cell layer, the zona glomerulosa. By polymerase chain reaction (PCR) techniques, aldosterone synthase expression has recently been described in blood vessels, heart, and brain, with demonstration of enzyme activity reported for the two former tissues. While possible extra-adrenal synthesis does not appear to contribute to circulating hormone levels, the extent to which it may support local tissue effects of aldosterone *in vivo* remains to be determined.

Regulation of Aldosterone Secretion

In vivo aldosterone secretion from the zona glomerulosa is predominantly and independently regulated by angiotensin II and plasma potassium concentrations. Adrenocorticotrophic hormone (ACTH) can also raise aldosterone secretion, but unlike the other two secretagogues, its action is not sustained. While a myriad of other possible modulators of aldosterone secretion have been reported, including endothelin, nitric oxide, and uncharacterized factors from the pituitary and adipose tissue, the relative importance of such inputs to pathophysiological control *in vivo* has not been established. Both experimentally and clinically, changes in angiotensin II and/or plasma potassium appear sufficient to explain changes in aldosterone secretion rates from nonneoplastic adrenals.

Mineralocorticoid Receptors: Cloning

Classical mineralocorticoid receptors binding aldosterone with high affinity and blocked by the antagonist spironolactone have been studied since the mid-1970s, with the human MR cloned and expressed by the late 1980s. The human MR comprises 984 amino acids and, like other members of the steroid/thyroid/retinoid/orphan receptor superfamily, has a domain structure that includes a ligand-binding domain (LBD) and a DNA-binding domain (DBD). Like other members of the receptor superfamily, MR act by regulating gene expression; sgk expression in A6 cells is actinomycin inhibitable, and aldosterone-induced sodium transport is both actinomycin and puromycin inhibitable in toad bladder models of mineralocorticoid action. Mineralocorticoid receptors are part of a subfamily with the receptors for glucocorticoids, progestins and androgens, sharing $\geq 50\%$ amino acid identity in the LBD and $\geq 90\%$ in the DBD.

Mineralocorticoid Receptors: Characterization

The initial MR cloning and expression studies also highlighted two questions regarding aldosterone action, questions that had been previously addressed by studies on MR in tissue extracts. First, when mRNA from a variety of rat tissues was probed with MR cDNA, the highest levels of MR expression were found in hippocampus rather than classic epithelial aldosterone target tissues. Second, when the affinity of various steroids was determined by their ability to compete for [3 H]aldosterone binding to expressed human mineralocorticoid receptors, cortisol was shown to have high affinity for MR, equivalent to that of aldosterone, and corticosterone (the physiological glucocorticoid in rat and mouse) slightly higher affinity. There are thus at least two operational questions, of which the first is the physiological role(s) of MR in nonepithelial tissues, such as hippocampus (and other brain areas and heart, for example). The second is how aldosterone can selectively activate MR, in epithelia or in nonepithelial tissues, in the face of at least equivalent receptor affinity and the much higher circulating levels of the physiological glucocorticoids.

Aldosterone Specificity-Conferring Mechanisms: Transcortin, 11 β HSD2

Differential plasma binding of steroids has long been recognized as one factor favoring aldosterone occupancy of MR. The physiological glucocorticoids cortisol and corticosterone circulate at least 95% protein bound, predominantly to the specific globulin transcortin but also to albumin; aldosterone has negligible affinity for transcortin and is only ~50% albumin bound in plasma, giving it an order of magnitude advantage in terms of plasma free to total concentrations. Second, the enzyme 11 β HSD2 is abundantly expressed in epithelial aldosterone target tissues. 11 β HSD2 has a very low K_m (high affinity) for cortisol and corticosterone, acting essentially unidirectionally to convert them to cortisone and 11-dehydrocorticosterone. These 11-keto congeners have very low affinity for MR, and when they do occupy MR, act as antagonists. Aldosterone, in contrast, is not so metabolized; its 11 β -OH group cyclizes in solution with the unique and very active aldehyde group at C18, forming an 11,18-hemiacetal and rendering aldosterone not a substrate for 11 β HSD2.

Apparent Mineralocorticoid Excess

The crucial role of 11 β HSD2 in conferring aldosterone specificity in otherwise nonselective epithelial

MR is underlined by the clinical syndrome of apparent mineralocorticoid excess (AME). In this rare autosomal recessive disorder, patients present with high blood pressure and marked sodium retention, despite low plasma levels of renin and aldosterone. The syndrome can be diagnosed by an abnormally high ratio of urinary free cortisol to cortisone, reflecting loss-of-function mutation of the sequence coding for 11 β HSD2. Under such circumstances the mutant enzyme shows poor or absent ability to convert cortisol to cortisone, and cortisol inappropriately activates MR, leading to uncontrolled sodium retention and hypertension. A milder version of the syndrome can be produced by licorice abuse, as the active principle of licorice (glycyrrhetic acid) blocks 11 β HSD2 activity, as does the erstwhile antipeptic ulcer drug carbenoxolone, the hemisuccinate of glycyrrhetic acid.

Extraepithelial Actions of Aldosterone

The physiological roles of extraepithelial MR and the extraepithelial effects of aldosterone have been elucidated only in part. Hippocampal MR appear involved in integration of baseline circadian ACTH secretion in response to stress; given the high reflection coefficient of aldosterone at the blood–brain barrier, it appears improbable that these receptors, unprotected by 11 β HSD2, are ever occupied by aldosterone. Other brain MR, in contrast, are clearly occupied and at least to some extent activated by aldosterone, being protected by 11 β HSD2. The amygdala, for example, express both MR and 11 β HSD2, and have been shown to be responsible for the aldosterone-induced increase in salt appetite in sodium deficiency or after sodium loss; interestingly, the amygdala appear within the blood–brain barrier, with no evidence for facilitated aldosterone access to MR. Activation of MR in the anteroventral third ventricle (AV3V) region (which is outside the blood–brain barrier) is necessary for mineralocorticoid-salt hypertension: intracerebroventricular infusion of MR antagonists abolishes the elevation of blood pressure following peripheral infusion of aldosterone to rats, or feeding a high-salt diet to salt-sensitive strains of rats. This has generally been interpreted as a direct role for aldosterone in modulating blood pressure via MR activation in the AV3V region; physiologically, however, this appears unlikely, and the MR activation putatively reflects glucocorticoid occupancy of the receptors under particular conditions.

Aldosterone, Cardiac Hypertrophy, and Cardiac Fibrosis

Aldosterone occupancy of cardiac MR has similarly been shown in a variety of experimental models to

produce cardiac hypertrophy and fibrosis. These effects are independent of hemodynamic changes, as clamping blood pressure by the concomitant infusion of intracerebroventricular MR antagonist does not alter the effects of peripherally infused aldosterone on cardiac hypertrophy and fibrosis. They are also crucially dependent on an aldosterone–salt imbalance; infusion of the same dose of aldosterone to rats fed a low-salt diet is not followed by increases in blood pressure or in cardiac hypertrophy and cardiac fibrosis. Cardiac MR, like those in the CNS, are normally unprotected by 11 β HSD2; the cardiac effects seem to require only a minority of MR to be occupied by mineralocorticoid, as shown in studies of transgenic mice expressing 11 β HSD2 specifically in cardiomyocytes. Importantly, and in contrast with epithelia, occupancy of extraepithelial MR by glucocorticoids does not mimic the effect of aldosterone. Also in contrast with the epithelial effects of aldosterone via MR, which have a time course of hours, the extraepithelial effects of aldosterone take days or weeks to be manifest: vascular inflammatory responses are seen after 1–2 days, increases in collagen type I and type III mRNA are seen by the third week of continuous aldosterone infusion, and plateau levels of blood pressure elevation are seen at 4–6 weeks. The mechanisms underlying these epithelial/extraepithelial differences in the action of aldosterone via identical MR are not understood, but presumably reflect at least in part tissue-specific differences in the coactivators, corepressors, and response elements involved.

Aldosterone: A Stress Hormone?

Aldosterone is a stress hormone depending on the definition of stress. Psychological or physical stressors that raise ACTH and adrenal catecholamine output do not lead to major or sustained elevations in aldosterone levels. Physiologically, aldosterone is raised in response to upright posture to defend intravascular volume; longer-term stressors, in terms of fluid and electrolyte balance (e.g., diarrhea, florid sweating, pregnancy, and lactation on a low-sodium diet) raise aldosterone to act in a tight feedback loop to retain sodium and water. Our renin-angiotensin-aldosterone system appears to have evolved in a context of sodium deficiency, which is often more of an issue for herbivores than for omnivores, and we have much less well developed mechanisms for suppressing aldosterone secretion than for elevating it. On contemporary salt intakes, our inability to lower aldosterone secretion commensurately may thus in a counterintuitive sense be in itself a stressor for the organism, which requires 2–5% of the normal modern salt intake except in response to the stress of

reproduction, gastrointestinal infection, or environmental extremes. The evolutionary craving for salt, and its routine addition to a range of foodstuffs, may thus constitute a stress in terms of the cardiovascular system, most noticeably hypertension, but with increasing evidence for direct effects of MR activation on the heart. The RALES trial, in which adding low-dose spironolactone to conventional ACE inhibitor/loop diuretic/digoxin therapy for heart failure substantially lowered mortality, would also seem to constitute evidence for MR activation operating as a stress mechanism in this sense.

MR Activation and Stress

As noted previously, 11 β HSD2 acts in epithelial tissues to allow aldosterone to selectively activate MR. In such tissues, however, the enzyme debulks intracellular glucocorticoid levels by 90%, rather than completely removes cortisol/corticosterone, so that their levels are still ~10 times those of aldosterone – and thus most MR in such tissues are normally occupied but not activated by glucocorticoids when the enzyme is operating. The key to this distinction appears to be the stoichiometric generation of NADH, which alters the redox state of the cell so that MR–glucocorticoid complexes are inactive: when 11 β HSD2 is blocked, levels of NADH fall, and the MR–glucocorticoid complexes are activated. This bivalent effect of cortisol can be reproduced in cardiomyocyte patch clamp studies, in which normally cortisol is an MR antagonist, but which activates MR when the redox state is altered by

installation of oxidized glutathione (GSSG). In pathophysiological terms, this suggests that the MR in nonepithelial tissues (for example, cardiomyocytes and most neurons) that are always essentially occupied by glucocorticoids may be activated by the metabolic or redox state of the cell, in particular, the generation of reactive oxygen species. If this is the case, then metabolic stress may be mediated via MR through a novel mechanism – that of activating a hitherto quiescent steroid–receptor complex, rather than by increasing the secretion rate and blood levels of a stress hormone such as cortisol.

Glossary

Allostasis

Achieving stability through change. A process that maintains homeostasis, defined as those physiological parameters essential for life, even though the set points and other boundaries of control may change with environmental conditions. There are primary mediators

of allostasis such as, but not confined to, hormones of the hypothalamic-pituitary-adrenal (HPA) axis, catecholamines, and cytokines. Allostasis also clarifies an inherent ambiguity in the term homeostasis by distinguishing between the systems that are essential for life (homeostatic) and those that maintain these systems in balance (allostatic). In contrast to homeostatic systems such as blood oxygen, blood pH, and body temperature, which must be maintained within a narrow range, allostatic (adaptive) systems have much broader boundaries of operation. Allostatic systems enable an organism to respond to its physical state (e.g., awake, asleep, supine, standing, exercising) and to cope with noise, crowding, isolation, hunger, extremes of temperature, physical danger, psychosocial stress, and microbial or parasitic infections. For example, blood pressure rises when an individual gets up in the morning and fluctuates with exercise and other demands of the waking period; these fluctuations make it possible for the individual to function in response to a changing social and physical environment.

Allostatic load and allostatic overload

The cumulative result of an allostatic state (e.g., fat deposition in a bear preparing for the winter, a bird preparing to migrate, or a fish preparing to spawn) is allostatic load. It can be considered the result of the daily and seasonal routines organisms have to obtain food and survive, and extra energy needed to migrate, molt, breed, etc. Within limits, they are adaptive responses to seasonal and other demands. However, if one superimposes on these additional loads of unpredictable events in the environment, disease, human disturbance (for animals in the wild), and social interactions, then allostatic load can increase dramatically. There are two distinctly different outcomes. First, if energy demands exceed energy income and what can be mobilized from stores, then type 1 allostatic overload occurs. For example, breeding birds use increasing food abundance in the spring to raise young. If inclement weather then increases the costs of maintaining homeostasis and the allostatic load of breeding, and at the same time reduces food available to fuel that allostatic load, then negative energy balance results in loss of body mass and suppression of reproduction. Another example is the mass movement of seabirds to

islands in the face of a severe storm that limits access to food. Characteristics of allostatic overload type 1 are that it results in acute increases in glucocorticoids (and possibly other mediators of allostasis) that then trigger facultative physiological and behavioral responses to redirect the individual from its daily or seasonal routine into survival mode. This reduces allostatic load to a level that can be fueled by resources available. Second, if energy demands are not exceeded and the organism continues to take in or store as much or even more energy than it needs, perhaps as a result of stress-related food consumption, choice of a fat-rich diet, or metabolic imbalances (prediabetic state) that favor fat deposition, then type 2 allostatic overload occurs. Besides fat deposition, there are other cumulative changes in other systems, for example, neuronal remodeling or loss in hippocampus, atherosclerotic plaques, left ventricular hypertrophy of the heart, glycosylated hemoglobin and other proteins by advanced glycosylation end products as a measure of sustained hyperglycemia, high cholesterol with low HDL, and chronic pain and fatigue, for example, in arthritis or psoriasis, associated with imbalance of immune mediators. Characteristics of allostatic overload type 2 are intermediate high levels of glucocorticoids (and other mediators of allostasis) that do not trigger facultative physiological and behavioral responses so that the individual remains stuck in a situation of high allostatic load with the deleterious events that follow. Allostatic overload type 2 can be alleviated by a change in environment, as well as by learning to avoid the source of allostatic load, for example, by a change in lifestyle. Medication may be the best recourse to redress the chronic imbalances in type 2 allostatic overload.

Allostatic state

An allostatic state is the sustained elevation or reduction of mediators of allostasis, such as glucocorticoids, catecholamines, or inflammatory cytokines. An allostatic state results in an imbalance of the primary mediators, reflecting excessive production of some and inadequate production of others. Examples are hypertension, a perturbed cortisol rhythm in major depression or after chronic sleep deprivation, chronic elevation of inflammatory cytokines and low cortisol in chronic fatigue syndrome,

imbalance of cortisol, corticotropin-releasing factor (CRF), and cytokines in the Lewis rat that increases risk for autoimmune and inflammatory disorders. Allostatic states can be sustained for limited periods if food intake and/or stored energy such as fat can fuel homeostatic mechanisms (e.g., a flock of birds flying away from a storm, or small mammals forced into a suboptimal habitat by an influx of predators). If imbalance continues for longer periods and becomes independent of maintaining adequate energy reserves, then symptoms of allostatic overload appear. Abdominal obesity is an example of this condition.

Turning On and Turning Off Allostasis

The body responds to challenge, whether exposure to danger, an infection, or a crowded and noisy neighborhood, by turning on an allostatic response, thus initiating a complex pathway for adaptation and coping, and then shuts off this response when the challenge has passed. The primary allostatic responses involve the sympathetic nervous system and hypothalamic-pituitary-adrenal (HPA) axis. Turning on these systems leads to release of catecholamines from sympathetic nerves and the adrenal medulla and the secretion of adrenocorticotrophic hormone (ACTH) from the anterior pituitary gland, which stimulates release of glucocorticoids from the adrenal cortex.

Turning off these responses leads to a return to baseline concentrations of glucocorticoids and catecholamines; this normally happens when the danger is past, the infection is contained, or the living environment is improved. As long as the allostatic response is limited to the period of challenge, protection via adaptation predominates over adverse consequences. However, over weeks, months, or even years, exposure to elevated levels of stress hormones (an allostatic state) can result in chronically high allostatic load and overload, types 1 and 2, with resultant pathophysiological consequences.

Causes of Allostatic Overload

Four situations can lead to allostatic overload, resulting in overexposure to stress hormones over time. The first is frequent stress. For example, blood pressure surges can trigger myocardial infarction in susceptible persons, and experiments in primates have shown that repeated blood pressure elevations over weeks and months accelerate atherosclerosis, which increases the risk of myocardial infarction.

Thus, the frequency of stressful events determines the degree of allostatic load, leading to increased exposure to hormones and other allostatic mediators.

A second cause of allostatic overload is the failure to habituate to repeated challenges, such as in some individuals' cortisol response during a repeated public speaking challenge.

The third cause of allostatic overload is an inability to shut off allostatic responses. This pertains to the termination of stress and also to the decline of these same hormones during the natural diurnal cycle. Blood pressure in some persons fails to recover after acute mental arithmetic stress, and hypertension accelerates atherosclerosis. Intense athletic training also induces allostatic load in the form of elevated sympathetic and HPA activity, which results in reduced body weight, amenorrhea, and the often-related condition of anorexia nervosa. Women with a history of depressive illness have decreased bone mineral density because the allostatic load of chronic, moderately elevated glucocorticoid levels that are associated with depression causes chronic, reduced levels of osteocalcin.

The fourth cause of allostatic overload is inadequate allostatic responses that trigger compensatory increases in other allostatic systems. When one system does not respond adequately to a stressful stimulus, the activity of other systems is increased because the underactive system is not providing the usual counterregulation. For example, if adrenal steroid secretion does not increase appropriately in response to stress, secretion of inflammatory cytokines (which are counterregulated by adrenal steroids) increases. In Lewis rats, the failure to mount an adequate HPA response results in increased vulnerability to autoimmune and inflammatory disturbances; thus, an infection or wound that causes an inflammation will lead to an increased inflammatory response.

Modulation of Allostatic Responses to Allostatic Load at Different Points in the Life Cycle or When Exposed to Different Social Signals

There is growing evidence that allostatic responses to standardized stressors are not constant throughout the life cycle. In vertebrates, the adrenocortical responses to stress may be elevated at one time of year and suppressed at others. Such modulation of allostasis is particularly evident when animals are reproducing. The reasons for this include very short breeding season, severe habitat, increasing age, and uncertain social status. Even though allostatic load increases in the same way or is even more severe, allostatic responses are changed temporarily.

In another model, rats that become subordinate in a psychosocial living situation called the visible burrow system have a stress-induced state of HPA hyporesponsiveness. In these rats, the HPA response to experimenter-applied stressors is very limited, and hypothalamic corticotropin releasing factor messenger RNA levels are abnormally low. Although specific health consequences are not yet known, these stress nonresponsive rats are believed to be the most likely to die over longer times in the visible burrow. Human counterparts of the state of HPA hyporesponsiveness include individuals with fibromyalgia and chronic fatigue syndrome.

Role of Behavior and Timing in Allostatic Overload

Anticipation, or lack of it, and worry can also contribute to allostatic overload. Anticipation is involved in the reflex that prevents us from blacking out when we get out of bed in the morning and is also a component of worry, anxiety, and cognitive preparation for a threat. Anticipatory anxiety can drive the output of mediators such as ACTH, cortisol, and adrenalin; thus, prolonged anxiety and anticipation is likely to result in allostatic load. For example, salivary cortisol levels increase within 30 min after waking in individuals who are under considerable psychological stress due to work or family matters. Moreover, intrusive memories from a traumatic event (e.g., as in post-traumatic stress disorder) can produce a form of chronic stress and can drive physiological responses.

Allostasis, allostatic states, and allostatic overload are also affected by health-damaging or health-promoting behaviors such as smoking, drinking, diet, and amount of exercise. These behaviors are integral to the overall notion of allostasis – how individuals cope with a challenge – and also contribute to allostatic overload by known pathways (e.g., a rich diet accelerates atherosclerosis and progression to non-insulin-dependent diabetes by increasing cortisol, leading to fat deposition and insulin resistance; smoking elevates blood pressure and atherogenesis; exercise protects against cardiovascular disease). Another example in nature is increased corticosterone production of songbirds in response to predator density, which could lead to long-term debilitation if the predator pressure remains constant.

Examples of Allostatic Overload

Cardiovascular and Metabolic Systems

In infrahuman primates, the incidence of atherosclerosis is increased among the dominant males of

unstable social hierarchies and in socially subordinate females. In humans, low job control predicts increased risk for coronary heart disease, and job strain (high psychological demands and low control) results in elevated ambulatory blood pressure at home and increased left ventricular mass index, as well as increased progression of atherosclerosis.

Quantifying allostatic overload, a major challenge, has been attempted with measures of metabolic and cardiovascular pathophysiology. In one study, 10 measures of activity of allostatic systems were assessed in aging subjects in 1988 and again in 1991. Allostatic overload was scored by determining the number of measures for which an individual was in the most extreme quartile, for example, the highest quartile in systolic blood pressure, overnight urinary cortisol, catecholamines, waist-hip ratio (WHR), glycosylated hemoglobin, the ratio of HDL to total cholesterol, or the lowest quartile in DHEA-sulfate or HDL cholesterol. For baseline data in 1988, subjects with higher levels of physical and mental functioning had lower allostatic load scores; these individuals also had less prevalent cardiovascular disease, hypertension, and diabetes. Moreover, among this higher functioning group, those with higher baseline allostatic load scores were more likely to experience incident cardiovascular disease between 1988 and 1991 and were significantly more likely to show declines in cognitive and physical functioning.

The Brain

Repeated stress has consequences for brain function, especially for the hippocampus, which has high concentrations of adrenal steroid receptors. The hippocampus participates in episodic and declarative memory and is particularly important for the memory of context, the time and place of events that have a strong emotional bias, and glucocorticoids are involved in consolidation of contextual fear conditioning. Impairment of hippocampal function decreases the reliability and accuracy of context memories, and this may lead an individual to miss important information and get into a more stressful situation. The hippocampus is also a regulator of the stress response and acts to inhibit shut-off of the HPA stress response.

The mechanism for stress-induced hippocampal dysfunction and memory impairment is twofold. First, acute stress elevates adrenal steroids, which suppresses the mechanisms in the hippocampus and temporal lobe that subserve short-term memory. Stress can impair memory acutely, but fortunately these effects are reversible and relatively short-lived. Second, repeated stress causes an atrophy of dendrites of pyramidal neurons in the CA3 region of the

hippocampus through a mechanism involving both glucocorticoids and excitatory amino acid neurotransmitters released during and in the aftermath of stress. This atrophy is reversible if the stress is short-lived, but stress lasting many months or years can kill hippocampal neurons. Stress-related disorders such as recurrent depressive illness, posttraumatic stress disorder, and Cushing's syndrome are associated with atrophy of the human hippocampus as measured by magnetic resonance imaging. It is not yet clear to what extent this atrophy is reversible or permanent.

Failure to turn off the HPA axis and sympathetic activity efficiently after stress is a feature of age-related functional decline in experimental animals and humans. Stress-induced cortisol and catecholamine secretion returns to baseline more slowly in some aging animals that at the same time show other signs of accelerated aging. One other sign of age-related impairment in rats is that the hippocampus fails to turn off the release of excitatory amino acids after stress; this may accelerate progressive structural damage and functional impairment. Long-term stress also accelerates the appearance of several biological markers of aging in rats, including the excitability of CA1 pyramidal neurons by a calcium-dependent mechanism and loss of hippocampal pyramidal neurons. An important factor may be the enhancement by glucocorticoids of calcium currents in hippocampus in view of the key role of calcium ions in destructive as well as plastic processes in hippocampal neurons.

One speculation is that allostatic overload over a lifetime may cause a loss of resilience in which allostatic systems wear out or become exhausted, leading to either failure to shut off or failure to respond. A vulnerable link in HPA regulation and cognition is the hippocampal region of the brain; according to the glucocorticoid cascade hypothesis, wear and tear on this brain region leads to dysregulation of the HPA axis as well as cognitive impairment. Supporting evidence comes from the finding that some, but not all, aging rats have impairments of both episodic, declarative, and spatial memory and HPA axis hyperactivity, both of which can be traced to hippocampal damage. Recent data in humans, showing hippocampal atrophy and cognitive impairment accompanying progressive elevations of cortisol levels over 4 years, suggests that similar events may occur in our own species.

Early stress and neonatal handling influence the course of aging and age-related cognitive impairment in animals. Early experiences are believed to set the level of responsiveness of the HPA axis and

autonomic nervous system. These systems overreact in animals subject to early unpredictable stress and underreact in animals exposed to the neonatal handling procedure. In the former condition, brain aging is accelerated, whereas in the latter, brain aging is reduced. Life span is also influenced by early-life differences in HPA reactivity: rats that show increased HPA reactivity to novelty as neonates have shorter life spans compared to rats with lesser HPA reactivity to novelty.

The Immune System

The immune system responds to pathogens or other antigens with its own form of allostasis that may include an acute phase response as well as the formation of an immunological memory. At the same time, the immune system reacts to other allostatic systems such as the HPA axis and the autonomic nervous system; these systems tend to contain acute phase responses and dampen cellular immunity. However, not all of the effects are suppressive. Acute stress causes lymphocytes and macrophages to redistribute throughout the body and to marginate on blood vessel walls and within certain compartments such as the skin, lymph nodes, and bone marrow. This trafficking is mediated in part by adrenal steroids. If an immune challenge is not encountered and the hormonal stress signal ceases, immune cells return to the bloodstream. However, when a challenge occurs, as in delayed-type hypersensitivity, acute stress enhances the traffic of immune cells to the site of acute challenge. The immune-enhancing effects of acute stress last for a number of days and depend on adrenal steroid secretion. Thus, acute stress has the effect of calling immune cells to their battle stations, and this form of allostasis enhances responses for which there is an established immunologic memory.

When allostatic overload is increased by repeated stress, the outcome is completely different; the delayed hypersensitivity response is substantially inhibited rather than enhanced. Such suppression of cellular immunity resulting from chronic stress leads to consequences such as increased severity of the common cold, accompanied by increased cold virus antibody titers.

Implications of Allostatic Overload in Human Society

The gradients of health across the range of socioeconomic status relate to a complex array of risk factors that are differentially distributed in human society.

For example, a study of elderly people who had a lifetime of sustained economic hardship pointed to a more rapid decline of physical and mental functioning.

Undoubtedly the best example is the Whitehall studies of the British Civil Service, in which stepwise gradients of mortality and morbidity were found across all six grades of the British Civil Service. Hypertension was a sensitive index of job stress, particularly in factory workers, in other workers with repetitive jobs and time pressures, and in workers whose jobs were unstable due to departmental privatization. Plasma fibrinogen, which predicts increased risk of death from coronary heart disease, is elevated in men in lower British Civil Service grades. In less stable societies, conflict and social instability have been found to accelerate pathophysiological processes and increase morbidity and mortality. For example, cardiovascular disease is a major contributor to the almost 40% increase in the death rate among Russian males in the social collapse following the fall of Communism. Blood pressure surges and sustained elevations are linked to accelerated atherosclerosis as well as increased risk for myocardial infarction.

Another stress-linked change is abdominal obesity, measured as increased WHR. WHR is increased at the lower end of the socioeconomic status gradient in Swedish males, and WHR also increases with decreasing civil service grade in the Whitehall studies. Immune system function is also a likely target of psychosocial stress, increasing vulnerability to infections such as the common cold, as noted previously.

Conclusions

Allostasis and allostatic load and overload are concepts that complement the concept of homeostasis by highlighting the paradoxical protective and damaging effects of the mediators of the stress response. These effects range from the short-term adaptation to danger or injury to the longer-term adaptations to adverse conditions associated with seasonal change, altered food supply, or crowding. They also include the diseases of modern life that are categorized as allostatic overload and represent the maladaptive extremes of responses such as fat deposition that have an adaptive role under conditions of varied food supply. By emphasizing the protective and damaging aspects of the same mediators, it is possible to highlight common mechanisms and interactions among the same mediators that underlie disorders such as diabetes, atherosclerosis, age-related cognitive impairment, autoimmune and inflammatory disorders, and immune dysfunction.

Glossary

Amyloid precursor protein (APP) A protein that is normally cut into smaller lengths by enzymes, resulting in the peptides amyloid beta (A-β)-40 and A-β-42. A-β-42 may circulate in small clumps (oligomers) and is believed to be neurotoxic and to be involved in the causation of Alzheimer's disease. The A-β peptides may be found later in Alzheimer's disease in larger clumps deposited in the brain, known as amyloid plaques.

Corticosteroid hormones Hormones produced by the adrenal gland as part of the stress response (principally cortisol in humans and corticosterone in rodents).

Declarative memory

Memories of facts and words (semantic memory) and personal events (episodic memory) that can be consciously recalled, as opposed to nondeclarative, implicitly learned procedural skills.

Delirium

A disturbance in consciousness, manifested by difficulties in focusing, sustaining, or shifting attention, with cognitive deficits. A delirium usually develops over a brief period of time and tends to fluctuate over the course of a day. It is directly caused by an active medical condition, such as an infection with a high fever, electrolyte disturbance, or liver or kidney failure.

Dementia

A syndrome of significant memory impairment compared with previous functioning, occurring with other cognitive deficits and not existing only during a period of delirium.

Hypothalamic-pituitary-adrenal (HPA) axis

The system that orchestrates the body's response to stress using hormones, with negative feedback mechanisms to allow the organism to return to baseline activation.

The Clinical Picture of Alzheimer's Disease

Dementia is a syndrome defined as the development of significant memory deficits together with other cognitive impairments, not occurring exclusively during a delirium. Of those diagnosed with dementia, between 50–60% have dementia of the Alzheimer's type, also called Alzheimer's disease (AD), a disorder characterized by symptoms with gradual onset but a

relentlessly progressive course. Early symptoms most prominently involve difficulties remembering recent events and forming new memories, and these are often accompanied by visuospatial and language problems. As the disease progresses, individuals slowly lose the ability to perform the activities of daily living, such as managing finances and driving a car. Eventually, attention, verbal ability, problem solving, reasoning, and all forms of memory become seriously impaired. Personality changes associated with the progression of AD may include increased apathy, anger, dependency, aggressiveness, and occasionally inappropriate sexual behavior; paranoid thinking is also not uncommon. In the latter stages of this disorder, individuals may be mute, completely confused, and bedridden. At this time, available treatments usually offer, at most, a temporary slowing of the symptomatic deterioration.

Early-onset AD is defined as a case in which the onset of dementia occurs at or prior to age 65; when symptoms first appear later in life it is referred to as late-onset AD. Somewhat complicating diagnostic specificity, AD may often co-exist with dementia or cognitive impairment due to another cause, most frequently vascular dementia (i.e., related to small or large strokes). Although making a probable diagnosis of AD is often not very difficult, it is a diagnosis that is only confirmed on autopsy. The prevalence of AD increases with age, from less than 1% of those age 65 to conservatively 13% of those age 85 and 23% of those age 90. As more individuals live to older ages, putting them at higher risk for this serious disorder, the economic burden of providing nursing home and other medical care to afflicted individuals, coupled with the tragic toll it takes on lives of the sufferers, their families, and other caretakers, constitutes a problem of ever-increasing magnitude.

Risk Factors for Alzheimer's Disease

Early-onset AD is infrequent, making up approximately 10% of AD cases seen in clinical practice. Most cases of early-onset AD are familial; they have been linked to specific identifiable mutations and have an autosomal-dominant pattern of inheritance with nearly full penetrance. Mutations in the Alzheimer precursor protein (APP) gene on chromosome 21, the Presenilin-1 gene on chromosome 14, and the Presenilin-2 gene on chromosome 1 have been identified, and they account for approximately 50% of all cases of early-onset familial AD. Also, most individuals who have trisomy-21 (Down syndrome), and therefore three APP genes instead of two, develop AD at relatively early ages, supporting the theory that the overexpression of the APP protein may be involved in causing AD.

In contrast, only a small number of late-onset AD cases are familial and no deterministic genetic mutations have yet been identified for late-onset sporadic AD, which accounts for more than 90% of AD cases. Clearly, genetic factors are not the sole cause of late-onset sporadic AD because the concordance rate for AD in monozygotic twins ranges from 31 to 59%. Instead, it appears that a number of genetic and environmental factors may increase the risk for this disorder. To date, the only genetic factor that has been associated with increased risk for late-onset AD is a form of the apolipoprotein E gene known as the APOE $\epsilon 4$ allele, which has a prevalence of approximately 25% in the general Caucasian population. Having one $\epsilon 4$ allele increases the risk of developing late-onset AD, and having two alleles (homozygosity) further increases the risk. In nondemented individuals, the APOE $\epsilon 4$ allele has been associated with poorer performance on delayed recall tasks and greater hippocampal atrophy compared with controls. The environmental risk factors for late-onset AD are diverse and incompletely characterized. Significant head trauma (i.e., with a loss of consciousness for an extended period) is a predisposing risk factor; higher education is an example of a protective factor. Women appear to be at a slightly higher risk of developing AD.

The Pathophysiology of Alzheimer's Disease

The characteristic features associated with AD include brain atrophy, amyloid plaques, and neurofibrillary tangles, and these abnormalities generally affect the medial temporal lobes the earliest and most intensely. Currently, there is compelling evidence that all types of AD, irrespective of age of onset, result from the neurotoxic effects of increased brain levels of soluble oligomeric forms of A- β peptides, derived from the amyloid precursor protein (APP), and from its aggregated forms (amyloid) as present in senile plaques and in the walls of small cerebral vessels. In cases of early-onset familial AD caused by genetic mutations, the increase in A- β is secondary to the increased production of the peptides A- β -40 and, especially, A- β -42 through the increased activity of β and γ secretases, two cleavage enzymes for APP. In contrast, in sporadic late-onset AD, it has been generally thought that decreased clearance of A- β is the proximate cause. In support of this hypothesis, brain regions associated with increased amyloid deposits in sporadic AD show lower levels of VPS26 and VPS35, two retromer proteins involved in the intracellular compartmental trafficking of the A- β peptides. Interestingly, there is recent evidence that the APOE $\epsilon 4$ allele may also increase A- β peptide

production, raising the possibility that increased A- β production contributes to the development of sporadic AD in elderly individuals with this allele. There is evidence that increased A- β peptide levels facilitate the abnormal phosphorylation of the τ protein, which in turn leads to its forming intracellular neurofibrillary tangles. This supports the general belief that the neurofibrillary tangles are a secondary phenomenon; however, memory deficits correlate more with the presence of neurofibrillary tangles than with plaques. The earliest pathological alterations of AD are usually seen in the entorhinal cortex and nearby CA1 subfield of the hippocampus, both structures in the medial temporal lobe critical for the formation of new memories, thereby explaining the prominent memory symptoms that are typically present as an initial symptom of AD.

AD is eventually accompanied by the pronounced degeneration of cholinergic neurons in the nucleus basalis with associated reduced levels of acetylcholine, and this loss seems to contribute significantly to memory dysfunction. The degeneration of dopaminergic neurons in the noradrenergic nucleus locus ceruleus, the serotonergic dorsal raphe nucleus, and the dopaminergic substantia nigra and the significant reductions in somatostatin-like immunoreactivity and corticotropin releasing hormone (CRH) immunoreactivity in the neocortical brain regions have also been demonstrated in AD and might contribute to the noncognitive symptoms associated with this disease.

Paradoxically, there is evidence, albeit indirect, that AD may be accompanied by overactivity of neuronal synapses using the neurotransmitter glutamate, possibly secondary to the loss of the high-affinity glutamate transporters that has been reported in AD. The overactivation of glutamate *N*-methyl-D-aspartate (NMDA) receptors produces excitotoxic effects, especially in areas such as the hippocampus and entorhinal cortex, in which the density of these receptors is high. These brain regions have been implicated in learning and memory and show profound abnormalities, including atrophy even in the earliest stages of AD, supporting a possible role for disturbances in glutamatergic neurotransmission in the cognitive and degenerative alterations associated with this disorder. There is also some empirical support for oxidative stress and inflammation having etiological roles in the pathogenesis of AD.

The Hypothalamic-Pituitary-Adrenal Axis in Normal Brain Functioning

The HPA manages the body's response to stress and is necessary for normal survival. When this system is activated, the paraventricular nucleus in the

hypothalamus releases CRH; this both activates the sympathetic nervous system and stimulates cells in the anterior pituitary to secrete adrenocorticotrophic hormone (ACTH), which stimulates cells in the adrenal cortex to synthesize and release corticosteroid hormones into the bloodstream. This complex orchestrated response acutely inhibits anabolic activity (growth-promoting functions), increases the opposite catabolic activities, and initiates the fight-or-flight reaction. This fight-or-flight reaction includes increases in heart rate and blood pressure, inhibition of the immune system, and experiential and behavioral activation. The corticosteroid secretion by the adrenal glands (principally cortisol in humans and corticosterone in rodents) provides negative feedback at the levels of both the hypothalamus and pituitary. Another important influence keeping this system in homeostatic balance is modulation provided by the hippocampus in the medial temporal lobe, a structure also critically responsible for acquiring and consolidating new declarative memories (semantic memories of facts and words and episodic memories of personal events, as opposed to nondeclarative, implicitly learned procedural skills).

Two types of corticosteroid receptors exist on the surface of neurons: type I or mineralocorticoid receptors (MRs), which have a higher affinity for corticosteroids, and type II or glucocorticoid receptors (GRs), which have a lower affinity. Under normal, non-stressful conditions, with low levels of circulating corticosteroids, mostly the higher-affinity MRs are stimulated, with GRs remaining mainly unaffected.

Stress and the Hypothalamic-Pituitary-Adrenal Axis

In the hippocampus, when the MRs are predominantly activated, the formation of new declarative memories is supported by the mechanism of long-term potentiation. Under low levels of acute stress, there may even be some improvement in this function. However, when stress levels and the associated increases in circulating corticosteroid levels cause more activation of the GRs, there is interference with forming new memories. This pattern of low levels of stress improving performance and higher levels of stress disrupting performance has sometimes been descriptively referred to as an inverted-U relationship. Slight elevations in stress hormones are also associated with enhanced attention and motivation, both important for performing well on memory and higher-order cognitive tasks but impairing the recall of previous memories. These latter actions appear to be mediated by both β -adrenergic and cholinergic receptors in the basolateral complex of the amygdala.

Stress and the Hypothalamic-Pituitary-Adrenal Axis in Animal Studies

Prolonged HPA overactivity is also associated with cognitive decline and hippocampal atrophy in rats. Rodents exposed to stress paradigms or administered large doses of corticosterone have been reported to have atrophy of the hippocampal neurons and increased sensitivity to toxins, but this could not be replicated in pigtailed macaque monkeys exposed to high doses of cortisone for 12 months. Species differences may be important because these primates proportionately have far fewer hippocampal GRs than rodents.

Stress and Hypothalamic-Pituitary-Adrenal Axis in Normal Aging

The hippocampus plays a major role in learning and memory performance, in particular in declarative (conscious and voluntary) memory. It is susceptible to damage from intense prolonged stress. Cortisol production increases during stress, and long-term exposure to high levels of cortisol causes atrophy and impaired neurogenesis in the hippocampus. There is also evidence of hippocampal atrophy as a function of aging, and HPA overactivity is associated with cognitive decline and hippocampal atrophy in normal elderly.

There are a variety of measures of HPA activity: simple plasma cortisol and salivary cortisol measures have been used, but there is much variation in these over the course of a day. Urinary cortisol may be a more reliable measure of cortisol secretion over time, and some studies have determined that cerebrospinal fluid (CSF) cortisol more accurately reflects cortisol levels in the central nervous system. Another widely used measure of HPA activity is the dexamethasone (DST) test (DST is a synthetic glucocorticoid). DST is typically administered to individuals in the evening, and plasma cortisol levels are measured the following day in the morning or afternoon. Ordinarily, DST suppresses the HPA axis, and plasma cortisol levels will be low the day after DST administration. Failure to suppress the HPA axis (nonsuppression) is evidence of a loss of normal feedback control and homeostasis.

There is some evidence suggesting gender differences in the role of cortisol overproduction in cognitive and memory dysfunction in normal elderly individuals. One study has found that increases in urinary cortisol excretion are significantly associated with declines in memory performance over 2.5 years in healthy elderly women but not in men. Furthermore, women who showed a decrease in urinary cortisol excretion showed significant improvement in memory performance over time. These findings

highlight the possibility that damage to the structure and functioning of the brain from hypercortisolemia might be reversible, at least for healthy elderly women, although it is believed that prolonged and repeated exposure to glucocorticoids increases the risk of irreversible damage.

Indeed, longitudinal examinations of cortisol levels and declarative memory performance reveal that elderly individuals with high and increasing cortisol levels over periods ranging from 1 to 3 years show significantly greater impairments in declarative memory performance and significantly greater hippocampal atrophy than do individuals who show decreases or low and smaller increases in cortisol levels over time. The amount of hippocampal atrophy in elderly individuals with high and increasing levels of cortisol was found to be equivalent to that of older adults exhibiting mild cognitive impairment (MCI). Although cortisol levels, on average, increase with aging, there is much interindividual variability in cortisol production in the elderly, with some individuals actually showing decreases in cortisol levels over time.

Stress and Alzheimer's Disease

Because older age, hypercortisolemia, and hippocampal atrophy are all associated with AD, the role of stress in AD pathology and memory dysfunction has logically attracted some attention. According to the glucocorticoid cascade hypothesis, hippocampal degeneration in AD might result in increased cortisol secretion, due to the loss of normal negative hippocampal feedback to the HPA axis. In turn, the overactive HPA system evident in AD could lead to additional neuronal degeneration, thereby inducing progressive cognitive impairment – potentially a vicious circle.

Memory deficits have also been found in the presence of other disorders that are associated with persistent HPA activation and high cortisol levels, such as Cushing's disease and major depressive disorder. One investigator found that, compared to matched controls, women with histories of recurrent major depression had smaller hippocampal volumes, the size of which were correlated with their lifetime duration of depression, and did more poorly on tests of verbal memory.

Most studies of individuals with AD have found them to have elevated post-DST cortisol levels compared to healthy controls. Increased HPA activity, as evidenced by elevated basal cortisol levels, elevated glucocorticoid activity, increased CSF cortisol levels, and hippocampal atrophy, have also been usually found to be positively associated with the degree of cognitive impairment in elderly individuals with AD.

A relevant variable also appears to be the presence of agitation, found to be more frequent in DST non-suppressors. In one small study that followed AD patients for up to 3 years, increased basal plasma cortisol levels were found to linearly correlate with decline in cognitive functioning.

A recent study demonstrated a relationship between APOE genotype and CSF cortisol levels in individuals with AD. Specifically, in analyses controlling for age, it was found that individuals with AD who had the APOE $\epsilon 4$ genotype had significantly higher cortisol levels than did individuals without the $\epsilon 4$ allele. Similar analyses performed with nondemented elderly individuals revealed only a trend for individuals with the $\epsilon 4$ allele to have higher CSF cortisol levels. These findings suggest that the APOE $\epsilon 4$ genotype might contribute to HPA axis dysfunction. However, CSF cortisol levels were not significantly correlated with measures of global cognitive status, although it is possible that CSF cortisol levels might be associated with more subtle changes in cognitive functioning.

Psychological Stress and the Hypothalamic-Pituitary-Adrenal Axis in Alzheimer's Disease

The evidence of a direct role of stress in AD onset remains limited and inconclusive. As previously noted, there are many studies reporting a significant association between acute and chronic stress with memory impairment, yet few studies have considered the role of elevated stress levels in the development of AD. In a longitudinal analysis of subjects' proneness to psychological distress and AD onset, investigators found that in analyses that accounted for depressive symptoms, for each 1-point increase on the distress-proneness scale there was a corresponding 6% greater risk of AD onset. Proneness to psychological distress was measured with a well-established index of neuroticism. Furthermore, greater proneness to psychological distress was associated with poorer levels of, and a greater decline in, global cognitive functioning. Additional analyses revealed an association between greater psychological distress and greater decline in episodic memory functioning. Specifically, decline was 16% greater for each 1-point increase on the distress proneness scale in episodic memory functioning. However, proneness to psychological distress was not associated with pathological AD as examined postmortem.

In a similar analysis examining distress-proneness and AD onset in a community sample of Caucasian and African American (49.8%) elderly individuals, it was found that individuals who scored in the ninetieth percentile or higher on a neuroticism index were

2.4 times more likely to develop AD over the course of 3–6 years. Additional analyses accounting for depressive symptoms or excluding individuals with depression at baseline did not alter the results. Although the researchers did not have postmortem data for AD pathology, the APOE genotype (a potential risk factor for AD) was available; and the researchers found no significant association between APOE genotype and distress-proneness in the full sample. Interestingly, the magnitude of the association between distress-proneness and AD onset was significantly different in Caucasian versus African American individuals. In the Caucasian sample, with each 1-point increase on the distress-proneness scale the odds of developing AD increased 12%. In contrast, the odds of developing AD in the African American sample increased only 2% for every 1-point increase on the distress-prone scale. These findings highlight the possibility of sociocultural differences in the association between stress and AD onset.

Other studies examining psychosocial stressors and AD onset have reported similar findings. For example, in a longitudinal analysis of psychosocial stressors and AD onset, when accounting for demographic factors, including education, individuals who reported psychosocial stressors as far back as childhood were found to have significantly higher rates of AD onset relative to individuals with fewer or no psychosocial stressors. Specifically, the incidence rate of AD over 9 years in individuals reporting no psychosocial stressors was 1.7%, and this rose to 5% in individuals reporting one or two and to 8.3% for individuals reporting three or more psychosocial stressors. The psychosocial stressors or risk factors that were considered included events from childhood (i.e., death of a parent and poverty), adulthood (i.e., death of a spouse, arduous manual labor, and serious illness in a child), and old age (i.e., deterioration in financial status and physical illness). Psychosocial stressors that were significantly associated with AD onset included the death of a parent during childhood, arduous manual labor, physical illness in a spouse during old age, and serious illness in a child (offspring). Possibly relevant to this finding is an earlier study reporting that, when accounting for education and alcohol consumption, men who had occupations involving manual labor were 5.3 times more likely to be diagnosed with late-onset AD than were men in nonarduous occupations. The finding that psychosocial stressors earlier in the life span might contribute to dysfunction in later life is also congruent with research using animal models in which earlier experiences altered noradrenergic and serotonergic functions in adulthood and the rate of aging.

A Possible Treatment Approach

An interesting avenue in exploring the role of stress hormones in AD is the potential therapeutic utility of corticosteroid receptor antagonists such as mifepristone (RU-486). In a pilot study in which participants were randomized to placebo or treatment with RU-486 for 6 weeks, participants taking RU-486 improved on measures of memory, whereas participants in the placebo condition declined. Other studies have also revealed that short-term use of RU-486 improves memory performance in bipolar patients but not for individuals with schizophrenia. Indeed, using a corticosteroid receptor antagonist to try to delay the onset or slow the progression of cognitive impairment and AD deserves further consideration.

Conclusion

Studies examining HPA dysfunction, cortisol levels, and indices of psychological distress have found significant associations with memory impairment, memory decline, AD, or AD onset. Although it appears that psychological distress, independent of depression, may play a role in AD onset, research on the biological mechanisms linking stress to AD onset remains inconclusive. HPA overactivity and high or increasing levels of cortisol seem to be associated with cognitive dysfunction and brain changes associated with AD, but it is unclear whether these impairments precede AD onset or are a function of the illness. Longitudinal research examining the biological mechanisms of stress and AD onset would be fruitful for further understanding the link between psychological stress and AD.

Effects of Chronic Stress

Glossary

Ambulatory blood pressure monitoring (ABPM)

A technique for measuring blood pressure over prolonged periods of time (typically 24 h) in free-living subjects. Most devices measure the blood pressure from a cuff placed on the upper arm inflated at regular intervals (usually every 15–20 min) by the monitor, which is a battery-operated device a little bigger than a portable radio.

Dippers and nondippers

Blood pressure normally decreases by at least 10% during the night in comparison with the average daytime level. The difference between the average daytime and nighttime blood pressure has been used to classify people as dippers (>10% difference) or nondippers (<10% difference).

White coat effect

The increase of blood pressure associated with the physician's office setting, usually expressed as the difference between the clinic and average daytime pressures.

White coat hypertension

Hypertension defined by a persistently elevated clinic or office blood pressure together with a normal blood pressure at other times (usually measured with ambulatory blood pressure monitoring).

Technique

Ambulatory blood pressure monitoring (ABPM) is performed using small fully automatic battery-operated monitors that weigh less than one pound and can be worn on a belt while subjects go about their normal daily activities. The monitor typically

contains a pump that inflates the blood pressure cuff at preset intervals, a pressure detection system (usually operating by the oscillometric method), and a memory chip for storing the readings. The cuff is usually placed on the nondominant arm above the elbow and is connected to the monitor by a thin tube. Subjects are asked to keep their arm still and by their side while a reading is taken. The monitors do not work reliably during vigorous activity (e.g., exercise) or in environments where there is a lot of noise or vibration. Subjects may be asked to keep a diary describing their activity, mood, and location at the time of each reading. Blood pressure during sleep can also be recorded. At the end of 24 h the subject returns and the readings are downloaded into a computer for analysis. Several types of monitor are available, but not all have been validated for accuracy according to standard protocols.

Advantages of Ambulatory Blood Pressure Monitoring

ABPM has revolutionized the study of the relationships between stress and blood pressure. Previously, reliance was made on blood pressure measured either in an office or in a laboratory setting. In the former case, a very limited number of readings is usually made, and the blood pressure that is recorded may represent the white coat effect rather than the effects of everyday stress. And while reactivity testing in the laboratory permits multiple measurements to be made during exposure to standardized stressors, the situation is artificial, and generalizability to blood pressure measured in real life is very poor. ABPM can give three different types of information relating to blood pressure: the average level, short-term changes, and the diurnal rhythm. Normally the blood pressure falls by about 10% during the night, but in about 25% of people the changes are smaller than this – the so-called nondipping pattern. There is now substantial evidence that the average level of blood pressure as measured by ABPM gives a better predictor of cardiovascular risk than conventional clinic measurements. In addition, nondippers have been reported to be at higher risk than dippers. The pathological significance of short-term blood pressure variability is unclear, although it is hypothesized that increased variability may be an independent risk factor.

White Coat Hypertension

One of the important phenomena identified by ABPM is white coat hypertension, which occurs in about 20% of patients with mild hypertension. Such patients usually have less target organ damage than patients with the same level of clinic pressure but whose pressure remains high outside the clinic, and they also appear to be at lower risk of cardiovascular morbidity. The origins of white coat hypertension are unexplained, but it is usually attributed to the stress associated with an encounter with a physician. It has been suggested that the phenomenon may be a conditioned response.

The Influence of Personality and Mood

ABPM can be used to measure blood pressure during normal daily activities, including work. By having subjects keep a diary of their activities and emotions it is possible to correlate behavioral factors and blood pressure. Thus, while anger is the mood that is associated with the greatest increase of blood pressure, blood pressure also increases when subjects report that they are happy as compared to having a neutral mood. There are also reports of associations between negative moods and ambulatory blood pressure. The analysis of such interactions requires that there is statistical control for other influences such as posture, location, and activity. A number of reports have found that subjects who score high on hostility report more negative moods and have higher blood pressures in association with them than subjects who are less hostile. Hostile subjects also have higher nocturnal blood pressure and show a more rapid increase on waking.

Effects of Acute Stress

Blood pressure is typically highest during the hours of work, which may be the result of both physical and mental activity being greater than at home. In men, blood pressure usually falls when they get home in the evening, but in women it may not do so, particularly if they have small children. The effects of commonly occurring activities on blood pressure are shown in [Table 1](#). A study of men working in machine shops found a significant correlation between the frequency of somatic complaints such as palpitations, fatigue, and dizziness and ambulatory systolic pressure. Paramedics show 10 mmHg higher blood pressures when they are in an ambulance and 7 mmHg elevations at the scene of an accident than during nonworkday activities.

Table 1 Average changes of blood pressure associated with 15 commonly occurring activities

<i>Activity</i>	<i>Systolic (mmHg)</i>	<i>Diastolic (mmHg)</i>
Meetings	+20.2	+15.0
Work	+16.0	+13.0
Transportation	+14.0	+9.2
Walking	+12.0	+5.5
Dressing	+11.5	+9.7
Chores	+10.7	+6.7
Telephone	+9.5	+7.2
Eating	+8.8	+9.6
Talking	+6.7	+6.7
Desk work	+5.9	+5.3
Reading	+1.9	+2.2
Business (at home)	+1.6	+3.2
Television	+0.3	+1.1
Relaxing	0	0
Sleeping	−10.0	7.6

Effects of Chronic Stress

Occupational stress has been investigated in several studies. In a study of 50 normotensive working women doing technical and clerical jobs, who also kept diaries describing their activities, emotions, and perceptions of stress, it was found that the average pressures were 116/78 mmHg at work, 113/74 mmHg at home, and 102/63 mmHg during sleep. The most powerful behavioral predictor of systolic pressure was the perception that one's job is stressful, which was associated with higher pressures in all three situations – at work, at home, and during sleep. The perception that there was more stress at work than at home on the day of the study was associated with higher systolic pressures at work, but not at home or during sleep. Potential sources of domestic stress were also related to blood pressure. Being married was associated with higher work diastolic pressures, while having children was associated with higher systolic and diastolic pressures both at work and at home. Women who reported higher levels of stress at home than at work also had relatively higher diastolic pressures at home than at work. Thus, single women whose main source of stress was at work showed a pattern similar to the one seen in men, while married women with children, whose level of stress may be higher at home, did not show the typical decrease of blood pressure when they returned home.

Young physicians, when on call for the emergency room, show an elevation of ambulatory blood pressure in comparison to a weekend day, which exceeded 10 mmHg for systolic pressure in 40% of cases. Blood pressure while asleep was not affected, however.

In this case the acute work stress raised the blood pressure during the exposure to stress, but to what extent this was due to mental as to opposed to physical activity is not clear. A very different picture is obtained with more chronic stress: subjects whose jobs are characterized as high strain (defined by a combination of high demands and low control) have elevated ambulatory blood pressures in comparison with subjects in less stressful jobs, not only during the hours of work, but also, more surprisingly, while they are at home and asleep. That this is a causal relationship is suggested by the finding that over a 3 year period those who remain in high-strain jobs show a persistent elevation of blood pressure, and those whose jobs become less stressful show a decrease of pressure. These results provide the strongest evidence to date that exposure to chronic stress can elevate the blood pressure throughout the 24 h period. Interestingly, there appears to be no relation between blood pressure and job strain in women, despite the fact that women are more likely than men to be in high-strain jobs. This might be because women react to different types of stress than men: another study found that lack of social support predicted ambulatory blood pressure in women, while hostility was a better predictor in men.

The Menstrual Cycle

Basic Embryology

Classification of Amenorrhea

Clinical Evaluation of Amenorrhea

Management of Amenorrhea

Glossary

Androgen insensitivity syndrome

A condition characterized by resistance to androgens, which subsequently leads males to develop into normal-appearing females. These patients are reared as females; they lack a uterus, fallopian tubes, and a vagina. Formerly known as testicular feminization.

Androgens
Aromatase

Male sex hormones.

Enzyme responsible for the conversion of androgens into estrogens.

Endometrial hyperplasia
Endometriosis

A condition characterized by the abnormal thickening of the endometrium.

A condition characterized by the presence of endometrial tissue outside the uterus, for example, on the bowel surfaces or ovary.

<i>Endometrium</i>	The membrane lining of the uterine cavity.
<i>Eugonadotrophism</i>	A condition characterized by normal levels of gonadotropins.
<i>Galactorrhea</i>	A condition characterized by milk discharge from the nipple.
<i>Hypergonadotropic hypogonadism</i>	A condition characterized by elevated gonadotropins due to ovarian failure and diminished ovarian hormone secretion.
<i>Hypogonadotropic hypogonadism</i>	A condition characterized by low gonadotropins due to alterations of the central nervous system and hypothalamic-pituitary axis, leading to diminished ovarian hormone secretion.
<i>Hysterosalpingogram</i>	An x-ray film of the uterus and fallopian tubes obtained after the instillation of dye in the uterine cavity. It is used to evaluate the contour of the uterine cavity and patency of the fallopian tubes.
<i>Menarche</i>	The first menstrual period.
<i>Müllerian agenesis</i>	A condition characterized by the lack of development of the uterus, fallopian tubes, cervix, and upper vagina.
<i>Polycystic ovary syndrome</i>	A disease characterized by menstrual disturbances, obesity, excessive androgen production, and polycystic ovaries.
<i>Primary amenorrhea</i>	A condition characterized by the absence of menstruation by age 16 in a phenotypic female.
<i>Secondary amenorrhea</i>	A condition characterized by the cessation of menstruation for 3–6 months in a female who has previously menstruated.
<i>Sexual ambiguity</i>	A condition characterized by difficulty in assessing sex based on physical features because the individual was born with genitalia and/or secondary sex characteristics that are determined to be neither exclusively male nor female or that combine features of the male and female sexes.
<i>Virilization</i>	A condition characterized by the abnormal development of masculine features in females such as hair growth, baldness, and deepening of the voice.

Introduction

Amenorrhea is the cessation of the menstrual flow. It can be a physiological finding, such as in pregnant or menopausal patients, or a pathological finding with a possible underlying medical condition. Because amenorrhea may be a sign of other medical illnesses, it is important to evaluate patients presenting with this problem. Amenorrhea may cause stress to patients because they may perceive a loss of their femininity due to the lack of cyclical menstruation, or it may be secondary to stressors the patient may be experiencing.

The Menstrual Cycle

In females, usually the first sign of pubertal development is breast development. This is followed by pubic hair growth, growth spurt, and, finally, menarche (the first menstrual flow). Menarche is usually reached between the ages of 8 and 13 years.

The menstrual cycle is a very complex, hormone-driven process. The hypothalamus first produces gonadotropin-releasing hormone (GnRH), which acts on the pituitary gland. In response to GnRH, the pituitary gland secretes luteinizing hormone (LH) and follicle-stimulating hormone (FSH). LH and FSH act on the different cells of the ovary to cause growth of the ovarian follicles and production of hormones, namely estrogen and progesterone.

The menstrual cycle is divided into two phases: the follicular phase, during which there is recruitment and growth of follicles, and the luteal phase, which occurs after the release of the mature follicle. Estrogen dominates the follicular phase, whereas progesterone dominates the luteal phase. These hormones also play a role in the endometrium; estrogen leads to the growth of the endometrial lining, whereas progesterone leads to its maturation. If pregnancy does not occur, progesterone levels drop, which causes the shedding of the endometrial lining, and thus a new cycle is initiated. This is the basis of the progestin withdrawal challenge.

Basic Embryology

Male and female gonads develop in response to the chromosomal makeup of the developing fetus. In males, the Y chromosome drives the development of the testes. The testes, in turn, produce a substance that inhibits the development of female internal genitalia, namely, the uterus, fallopian tubes, and vagina. The testes also produce testosterone, which is responsible for the development of the male internal genitalia. Testosterone is also converted to another hormone, dihydrotestosterone, which leads to the development of the male external genitalia.

Unlike in males, in females there are no substances identified yet that drive genital development. In the absence of a Y chromosome, the internal and external genitalia are female. Two X chromosomes are required for normal ovarian development.

Classification of Amenorrhea

There are a number of causes of amenorrhea, and some are related to stress. The usual definition of amenorrhea is the cessation of menstrual flow.

Women who fail to menstruate by age 16 are often considered to have primary amenorrhea, whereas those who have previously been menstruating and now exhibit at least 3 months of amenorrhea are considered to have secondary amenorrhea. In this evaluation, women who present with delayed puberty also have amenorrhea and should not be considered as a separate entity. Women who present with sexual ambiguity since birth or significant virilization may also present with amenorrhea, but they should be evaluated as separate disorders. Using this approach, the diagnosis and treatment is somewhat simplified. It should be pointed out that classifications consisting of primary and secondary amenorrhea are not used here because they do not describe the pathophysiology; the classification chosen is presented in [Table 1](#).

The largest category is chronic anovulation, which includes women who have the ability to ovulate but do not. This category is subcategorized into women who are producing estrogen (eugonadotrophism) and those who are not producing estrogen (hypogonadotropic hypogonadism). A second category is ovarian failure (hypergonadotropic hypogonadism), in which the germ cells are usually absent. The third category comprises abnormalities and defects in the development of the female reproductive tract.

Chronic Anovulation

The major cause of amenorrhea is chronic anovulation. In this disorder, women have ovaries and follicles but for various reasons do not ovulate normally. With appropriate therapy, these women can ovulate and later conceive. In women with chronic anovulation, the ovaries do not secrete estrogen and progesterone in the normal cyclic pattern. In order to differentiate between women who produce estrogen from those who do not, a progestin challenge is administered either orally or intramuscularly. Women who exhibit bleeding after receiving an oral or intramuscular progestin challenge are producing estrogen and fall into the category of chronic anovulation with estrogen present; women who fail to exhibit a menstrual bleed after a progestin challenge have low levels of estrogen and are categorized as chronic anovulation with estrogen absent.

Chronic anovulation with estrogen present Women with chronic anovulation who experience withdrawal menstrual bleeding following a progestin challenge and exhibit normal FSH levels are said to be in a state of chronic estrous due to acyclic production of estrogen. The ovarian follicles of women with this disorder do not secrete estrogen but instead secrete androgens such as androstenedione, which is converted in

the peripheral tissues by extraglandular aromatase into the weaker estrogen estrone. This condition may be due to problems primarily in the ovary or in the hypothalamic-pituitary-gonadal feedback loops. The consequence is that these women fail to ovulate and produce estrogen and do not experience cyclic withdrawal bleeding.

The primary cause of chronic anovulation with estrogen present is polycystic ovarian syndrome (PCOS). PCOS is a complex disorder (probably inherited and perhaps related to insulin resistance) characterized by the development of hirsutism, androgen excess, obesity, and menstrual disturbances including amenorrhea, oligomenorrhea, or dysfunctional uterine bleeding at the time of expected puberty. The clinical picture varies and laboratory tests may be helpful but are only supportive in confirming the diagnosis. In the majority, but not in all, women with PCOS, plasma LH levels are elevated while the plasma FSH levels are normal or low. These findings have led some to suggest that a ratio of LH to FSH of greater than 2 to 3 may be a useful laboratory distinction; however, the evaluation of a single sample of gonadotropins may lead to the wrong diagnosis and only 80% of women may exhibit this finding. In addition, the majority of women with PCOS have moderately elevated serum androgen levels. An ultrasound demonstrating multiple superficial small follicles surrounding the surface of the ovary in a ringlike pattern associated with increased stromal density in a woman with amenorrhea appears to be the best test to confirm the diagnosis. However, as stated previously, the diagnosis of PCOS syndrome is not based on pathological changes in the ovaries or plasma hormone abnormalities but is primarily based on the clinical evidence of chronic anovulation with varying degrees of androgen excess and menstrual disturbances. New criteria put forth for the diagnosis of PCOS includes positive findings in two of the following findings: (1) clinical or biochemical evidence of hyperandrogenism, (2) irregular menstrual cycles with oligo- or anovulation, and (3) evidence of polycystic ovaries on sonography. The etiology of this disorder is multifactorial and is not yet clearly understood.

Chronic anovulation with estrogen present, obesity, hirsutism, and even polycystic ovaries can be seen in a variety of other endocrine disorders in addition to PCOS (see [Table 1](#)). These women may present with Cushing's syndrome, hyperthyroidism, hypothyroidism, and/or late adult-onset adrenal hyperplasia due to 21-hydroxylase or 11 β -hydroxylase deficiency. Rarely, patients with chronic anovulation with estrogen present can present with ovarian tumors such as a Brenner tumor or cystic teratomas and ovarian

Table 1 Classification of amenorrhea^a

Chronic anovulation with estrogen present		
PCOS		
Adrenal disease	Cushing syndrome Adult-onset adrenal hyperplasia	
Thyroid disease	Hypothyroidism Hyperthyroidism	
Ovarian tumors	Granulosa-theca cell tumors Brenner tumors Cystic teratomas Mucinous/serous cystadenomas Krukenberg tumors	
Chronic anovulation with estrogen absent (hypogonadotropic hypogonadism)		
Hypothalamic	Tumors	Craniopharyngioma Germinoma Hamartoma Hand-Schüller-Christian disease Teratoma Endodermal sinus tumors Metastatic carcinoma Tuberculosis Syphilis Encephalitis/meningitis Sarcoidosis Kallmann syndrome GnRH receptor mutations Idiopathic hypogonadotropic hypogonadism Chronic debilitating disease
	Infection and other disorders	Stress Weight loss/diet Malnutrition Psychological eating disorders (anorexia nervosa, bulimia) Exercise Pseudocyesis Prolactinomas Other hormone-secreting pituitary tumors (ACTH, TSH, GH, gonadotropin) Nonfunctional tumors (craniopharyngioma) Metastatic carcinoma Empty sella Arterial aneurysm Sheehan syndrome Panhypopituitarism Sarcoidosis Hemochromatosis Lymphocytic hypophysitis
	Functional	
Pituitary	Tumors	
	Space-occupying lesions	
	Necrosis	
	Inflammatory/infiltrative	
	Gonadotropin mutations (FSH)	
Ovarian failure (hypergonadotropic hypogonadism)		
Gonadal agenesis		Turner syndrome 45,X Mosaicism
Gonadal dysgenesis	Abnormal karyotype Normal karyotype	Pure gonadal dysgenesis (46,XX; 46,XY, Swyer syndrome)
Ovarian enzymatic deficiency	17 α -Hydroxylase deficiency 17,20-Lyase deficiency Aromatase deficiency	
Premature ovarian failure	Idiopathic – premature aging Injury	Mumps oophoritis Radiation Chemotherapy

Continued

Table 1 Continued

	Resistant ovary	Idiopathic Mutations of FSH receptor Mutations of LH receptor
	Autoimmune disease Galactosemia	
Anatomic defects (outflow tract)	Labial agglutination/fusion Imperforate hymen Transverse vaginal septum Cervical agenesis – isolated Cervical stenosis – iatrogenic Vaginal agenesis – isolated Müllerian agenesis (Mayer-Rokitansky-Kuster-Hauser syndrome) Complete androgen resistance (testicular feminization) Endometrial hypoplasia or aplasia – congenital Asherman syndrome (intrauterine synechiae)	

^aNot including disorders of congenital sexual ambiguity. ACTH, adrenocorticotrophic hormone; FSH, follicle-stimulating hormone; GH, growth hormone; GnRH, gonadotropin-releasing hormone; LH, luteinizing hormone; PCOS, polycystic ovarian syndrome; TSH, thyroid-stimulating hormone.

cancers in which the ovary and/or tumor secrete increased amounts of androstenedione, which aromatize in extraglandular sites to estrogen. As a result, such patients may present with a pattern similar to that of a woman with PCOS that resolves at the time of the removal of the tumor or the treatment of the primary disorder. It is thus important to rule out these conditions first, prior to making a diagnosis of PCOS.

Chronic anovulation with estrogen absent Women with chronic anovulation with estrogen absent due to low or absent estrogen production fail to experience withdrawal bleeding or experience only vaginal spotting following a progestin challenge. Usually the FSH level is either in the normal or low range. This is an important point because evaluating just the FSH level alone (if within the normal range, for example, 4–8 IU l⁻¹) does not confirm the cause of amenorrhea. Chronic anovulation with estrogen absent is a result of hypogonadotropic hypogonadism, which is secondary to organic or functional disorders of the central nervous system (CNS) and hypothalamic-pituitary axis. It may be clinically helpful, but not always practical, to subdivide these into hypothalamic and pituitary causes (see [Table 1](#)). Hypothalamic tumors and other destructive disorders of the hypothalamus are relatively rare causes of amenorrhea and require radiographic evaluation such as a computerized axial tomography (CAT scan) or magnetic resonance imaging (MRI). In women with tumors, headaches and other neurological symptoms or signs are often present.

The most common cause of chronic anovulation with estrogen absent is a functional disorder of the hypothalamus or CNS in the presence of a normal MRI or CAT scan. In these cases, the cause of chronic anovulation is one of exclusion. A history of stress or a stressful event can often be obtained, which can include the loss of a loved one, entering a stressful work environment, or going off to college. In these cases, the stress reduces the hypothalamic secretion of GnRH, leading to reduced gonadotropin (FSH and LH) secretion followed by reduced ovarian estrogen secretion, resulting in amenorrhea. This can happen even in women with normal body weight.

Other causes related to stress and emotional disorders include weight loss and dieting, which are particularly common in young teenage girls. The most severe form of weight loss-induced amenorrhea is in anorexia nervosa, characterized by distorted attitudes toward eating and weight, self-induced vomiting, extreme emaciation, and distorted body images. Women who excessively exercise, particularly in such activities as marathon running, ballet dancing, or, more recently, working out in the gym with weights and using steroids to reduce their percentage of body fat, may develop amenorrhea. Amenorrhea is more likely to develop in women with a previous history of abnormalities in menstruation prior to the onset of excessive exercise or weight loss. It is known that women who develop amenorrhea associated with stress, exercise, or dieting exhibit alterations in the menstrual cycle that can be associated with normal

cyclic bleeding early in the onset of the increased exercise, weight loss, or dieting. Later, as the disorder progresses, problems in the production of progesterone during the luteal phase occur, followed by anovulatory cycles associated with oligomenorrhea and, finally, the development of amenorrhea. In some of these women a withdrawal bleed after progestin challenge may occur in the anovulatory phase, with some estrogen being produced, but in most women the failure to exhibit a withdrawal bleed following a progestin challenge suggests that the disease is more severe. If untreated, it may lead to problems associated with estrogen deficiency such as osteoporosis. Following a reduction of stress or exercise and increased weight gain, we may see a reversal from amenorrhea to ovulatory menstrual cycles, requiring no further treatment.

Other chronic debilitating diseases such as acquired immunodeficiency syndrome (AIDS), malabsorption, or cancer may result in hypogonadotropic hypogonadism. A relatively rare cause of hypothalamic amenorrhea in women is due to Kallmann's syndrome, which has been shown to be associated with defects in olfactory bulb development. It is known that GnRH neurons develop in this same rostral part of the brain as the olfactory bulbs. Thus, women with Kallmann's syndrome exhibit not only low gonadotropins and amenorrhea but also a lack of the sense of smell, or anosmia. As stated previously, the diagnosis of functional disorders of the CNS and hypothalamic-pituitary axis resulting in amenorrhea may be suggested by the patient's history, but it usually requires some form of imaging using MRI or CAT scan.

Disorders of the pituitary include not only tumors but also Sheehan's syndrome (postpartum necrosis of the pituitary due to hemorrhage), spontaneous necrosis of the pituitary, congenital absence of the pituitary, empty sella, and inflammatory or infiltrative disorders (see Table 1). However, the most common causes of amenorrhea associated with the pituitary are disorders associated with increased prolactin secretion. These women present with amenorrhea plus galactorrhea associated with an increased prolactin level. In women with amenorrhea and elevated prolactin levels, imaging of the pituitary is required and a thyroid-stimulating hormone (TSH) level is obtained as well. Hyperprolactinemia and galactorrhea may also be associated with taking medications, including psychoactive medications such as tricyclic antidepressants, phenothiazines, amphetamine, haloperidol, and chlorpromazine and antihypertensive medications such as verapamil and α -methyldopa. Hyperprolactinemia and galactorrhea may also be seen with recent breastfeeding. The majority of women with hyperprolactinemia do not exhibit demonstrable pituitary

tumors. Thus, there is some controversy about the level of serum prolactin at which head imaging should begin; some have suggested prolactin levels exceeding $50 \mu\text{g l}^{-1}$. Women with prolactin levels greater than $50 \mu\text{g l}^{-1}$ have approximately a 20% chance of presenting with a pituitary tumor, whereas those who have $100 \mu\text{g l}^{-1}$ have a 50% risk; those with over $200 \mu\text{g l}^{-1}$ have an approximately 90–100% chance of harboring a prolactin-secreting tumor.

Ovarian Failure

Ovarian failure in women is associated with increased gonadotropins in response to low or no secretions from the ovary, and hence the term hypergonadotropic hypogonadism is often used. The development of amenorrhea and hypoestrogenism associated with elevated gonadotropins prior to the age of 40 defines ovarian failure. However, it should be pointed out that cessation of ovarian function due to loss of germ cells and follicles in the ovary can occur at any age, even *in utero*, such as in gonadal dysgenesis or ovarian agenesis. When ovarian failure occurs prior to puberty, the presentation is that of a phenotypic female with primary amenorrhea and lack of secondary sexual development. When it occurs after pubertal development, the presentation is secondary amenorrhea with the primary complaint being hot flashes.

As is true for disorders of chronic anovulation, ovarian failure can result from several causes (see Table 1). These include gonadal agenesis or dysgenesis. Gonadal dysgenesis can be associated with normal or abnormal karyotypes. Women harboring Y chromosome material have an increased risk of gonadal tumors, and the gonads should be removed. Rare causes of ovarian failure include 17α -hydroxylase deficiency, resistant ovary syndrome, autoimmune disorders associated with galactosemia, and iatrogenic causes due to chemotherapy or radiation therapy. The diagnosis of ovarian failure should be suspected in all cases of primary amenorrhea and sexual infantilism and in women with secondary amenorrhea who develop hot flashes and other signs of estrogen deficiency. As stated earlier, this is confirmed by documenting an increased FSH at the menopausal range (i.e., $>30\text{--}40 \text{ IU l}^{-1}$).

Female Reproductive Tract Defects

Defects of the female reproductive tract can result in amenorrhea either from obstruction or the absence of endometrial tissue. Some of these conditions may be developmental and some may be due to iatrogenic causes. Women with anatomical defects have normal ovaries and ovarian function and develop secondary sexual characteristics. Ovulation can be proven by changes in the basal body temperature or by elevated

serum progesterone levels in the luteal phase of the menstrual cycle. These women also have a normal female 46,XX karyotype.

The logical approach to the evaluation and classification of anatomic defects is to start from the lowest entry at the opening of the reproductive tract and move upward. Thus, anatomic causes include labial agglutination or labial fusion and imperforate hymen. If the obstruction is farther up into the vagina, it is known as a transverse vaginal septum. Rarely, a complete absence of the cervix may be encountered. Women with all these conditions often present with increasing abdominal pain resulting from the accumulation of blood behind the obstruction. In such instances the pain is cyclic and predictable in nature, and it is associated with the onset of menstruation. If the diagnosis is delayed, endometriosis, adhesions, and infertility may result.

There are two additional disorders that are not associated with obstruction and pain but result from lack of development of the uterus and vagina: Müllerian agenesis or dysgenesis associated with a 46,XX karyotype and androgen insensitivity syndrome (formerly known as testicular feminization, in which there is a testis and a 46,XY karyotype). The diagnosis of androgen insensitivity is easily confirmed by the observation of the absence of pubic and axillary hair due to the androgen resistance and the finding of male-level testosterone on laboratory analysis. Individuals with androgen insensitivity should have their testes removed to prevent tumor development following the completion of breast development, which occurs at ages 12–14.

In rare instances, a woman may have both the absence of the uterus and the lack of female secondary sexual characteristics. In such individuals, a karyotype should be obtained. Individuals with a 46,XY karyotype have androgen deficiency, most commonly due to 17 α -hydroxylase deficiency, testicular regression, or gonadal dysgenesis. Those with the 46,XX karyotype have Müllerian agenesis plus another disorder such as ovarian failure and/or hypogonadotropic hypogonadism.

In addition, reproductive tract defects may also be due to iatrogenic causes such as scarring and stenosis of the cervix following dilation and curettage, conization, laser, or loop electrosurgical excision procedure (LEEP) used to treat cervical dysplasia. The destruction of the endometrium following a vigorous curettage after postpartum hemorrhage or therapeutic abortion or subsequent infection associated with a missed abortion results in scar tissue or uterine synechiae (Asherman's syndrome). The diagnosis of this defect is rare in the absence of a previous surgical procedure or pregnancy.

The diagnosis of female reproductive tract defects is established by history and physical examination. The presence of a labial agglutination, fusion, imperforate hymen, and transverse vaginal septum are easily recognized. An ultrasound can be obtained to confirm the location of the blockage and the presence or absence of the uterus. To evaluate and confirm the diagnosis of Asherman's syndrome, a hysteroscopic procedure or occasional hysterosalpingography may be indicated. Occasionally, laparoscopy may be required to confirm the final diagnosis of the reproductive tract anomaly.

Clinical Evaluation of Amenorrhea

The evaluation of amenorrhea should begin with a thorough medical history and physical examination. If a woman presents with primary amenorrhea and absence of secondary sexual characteristics, this may suggest a primary gonadal problem or ovarian failure. In contrast, if a woman presents with previous regular menstrual periods but develops amenorrhea following a dilation and curettage for hemorrhage, this suggests a diagnosis of uterine adhesions. The evaluation of amenorrhea requires a knowledge of the classification in [Table 1](#). A flowchart to aid in evaluating women with amenorrhea is presented in [Figure 1](#). This evaluation includes women with a female phenotype but excludes women with disorders of virilization or sexual ambiguity. The laboratory tests required include a pregnancy test and tests for levels of FSH, prolactin, and TSH. We find it helpful to evaluate the estrogen status based on the progestin withdrawal test. This is helpful prior to determining therapy for infertility as well. Evaluation of the estrogen status includes two parts: (1) the physical examination of the patient, looking for signs of previous estrogen secretion such as breast development and current estrogen secretion, which includes the presence of a well rugated, moist vagina with abundant clear stretchable cervical mucus (known as spinnbarkeit). The estrogen status can be confirmed by a progestin challenge using medroxyprogesterone acetate (5–10 mg once or twice daily for 5 days) or progesterone in oil (100–200 mg) administered intramuscularly, particularly when patient compliance is an issue. It should be pointed out that Depo-Provera should not be used because this, in fact, causes amenorrhea. The one exception to this overall evaluation is a woman who is known on physical examination to have an absent uterus; in this case it is more prudent and cost effective to perform a few tests such as a chromosomal analysis to differentiate Müllerian agenesis from complete androgen insensitivity syndrome.

Following the initial visit, the patient returns and the physician evaluates the levels of FSH and prolactin and the response to the progestin challenge. If the FSH is elevated, the evaluation is directed to ovarian failure or hypergonadotropic hypogonadism. However, if the FSH is low or normal, then the evaluation of the progestin challenge test is used to differentiate the two categories of chronic anovulation. Finally, if the serum prolactin is elevated, the TSH level should be measured and the pituitary further evaluated by either an MRI or CAT scan.

The majority of women with significant elevations of prolactin do not respond to a progestin challenge and thus are included in the category of chronic anovulation with estrogen absent. Such women should experience withdrawal bleeding following a cycle of estrogen plus progestin, but this test and its results are somewhat confusing because a high percentage of women do not bleed after one cycle of therapy. An evaluation of the outflow tract or reproductive tract is made on physical examination and if needed by hysterosalpingography, ultrasound, or hysteroscopy. During the physical examination, if the patient exhibits a vagina, a patent cervix that can be confirmed by uterine sounding (placing an instrument through the cervix into the uterine cavity), and a uterus without a history of pregnancy or operative procedure, a disorder of the female reproductive tract is unlikely. After disorders of the reproductive tract have been ruled out, a normal or low FSH level indicates a

disorder of the hypothalamus or pituitary. Most of these women have functional disorders of the hypothalamus, although lesions of the hypothalamus and pituitary may be present. The use of an MRI or CAT scan depends on the history, clinical presentation, and prolactin level. Overall, the flowchart presented in [Figure 1](#) is quite useful in the majority of cases, and the diagnosis is simplified and easily obtained.

Management of Amenorrhea

In general, the management of amenorrhea depends on the cause and on the current desires of the patient.

Chronic Anovulation

The treatment of women with chronic anovulation can be subdivided as before into treatment for those who are making estrogen and for those who are not. In women who are producing estrogen but are not ovulating, the treatment depends on the desires of the patient. If the patient is obese, weight loss should be encouraged, and this may in fact improve the overall clinical situation, including insulin resistance, if present, and hypercholesterolemia. Recent evidence has also shown that metformin, an oral hypoglycemic agent, may reduce insulin resistance, improve hirsutism, and cause the resumption of menses. If the woman is not hirsute and does not desire pregnancy, monthly withdrawal menses should be induced by either progesterone therapy or, more simply, using

Figure 1 Suggested flow chart to aid in the evaluation of women with amenorrhea. FSH, follicle-stimulating hormone; PCOS, polycystic ovarian syndrome; PRL, prolactin; R/O, rule out.

oral contraceptive pills, which reduces the risk of hemorrhage (i.e., dysfunctional uterine bleeding and endometrial neoplasia). On the other hand, if the woman is hirsute but does not desire pregnancy, excess male hormone production can be suppressed through oral contraceptive pills and/or antiandrogens. Oral contraceptive pills are also indicated if there are disorders in menstruation (i.e., dysfunctional uterine bleeding). Finally, if pregnancy is desired, ovulation can be induced with either clomiphene citrate, metformin, gonadotropins, or, occasionally, laparoscopic ovarian wedge resection or drilling.

In those women who are not making estrogen with chronic anovulation, the treatment should be directed at eliminating the primary cause such as weight loss, exercise, or stress. Treatment in women with amenorrhea and low estrogen should be aggressive because delayed treatment can lead to reduced body mass development and early osteoporosis. In women with elevated prolactin levels in the absence of prolactin-secreting tumors, cyclic estrogen–progestin therapy or, more commonly, oral contraceptive pills can be prescribed. Oral contraceptive pills and hormone replacement therapy not only prevent bone loss but also maintain secondary sexual characteristics. If pregnancy is desired, it is important that body weight and nutritional requirements for the potential developing fetus be returned to normal prior to the induction of ovulation. But if the amenorrhea persists in spite of the reduction in stress and increase in body weight and percentage of body fat, then gonadotropins or pulsatile GnRH therapy is often successful in inducing ovulation and pregnancy. In women who present with pituitary tumors that secrete prolactin, the treatment of choice is pharmacological, using dopamine agonists such as bromocriptine or cabergoline.

Ovarian Failure

Most cases of gonadal or ovarian failure are permanent, and patients should be started on hormone replacement therapy, particularly estrogen, as soon as possible. Again, estrogen maintains secondary characteristics and prevents premature osteoporosis. If the diagnosis of gonadal failure is made in a woman prior to breast development such as in Turner's syndrome, a regimen of low-dose estrogen gradually increased over a period of time may be important in producing normal breast development. Growth hormone may also be used prior to estrogen therapy in achieving greater height, if indicated. In women with gonadal dysgenesis, estrogen treatment begins with low-dose (i.e., conjugated) estrogens (0.3 mg) for 3–6 months, slowly increasing the dosage from

0.625 to 1.25 mg over 1 year to augment breast development. It is necessary to initiate progestin therapy after approximately 1 year of estrogen therapy to induce withdrawal bleeding to prevent endometrial hyperplasia. However, if progestin is started prior to the initiation of breast development, then breast development may be abnormal. Women with disorders such as 17 α -hydroxylase deficiency should be treated with glucocorticoids as well as with hormone therapy. Women with autoimmune ovarian failure have been treated with a variety of medicines, but none appears to be successful, so hormone replacement therapy appears appropriate. Occasionally, the repositioning of the ovary or oophoropexy may be helpful prior to women receiving radiation therapy. In addition, it has been hypothesized, but not proven, that pretreatment with LH-releasing hormone analogs or oral contraceptive pills prior to chemotherapy may be successful in maintaining ovarian function.

Women with amenorrhea due to ovarian failure are rarely able to conceive on their own. In some cases, ovarian follicular depletion may not be complete and spontaneous ovulation and a rare pregnancy may occur. The current treatment for infertility due to ovarian failure is to obtain donor oocytes from normal ovulatory women, followed by *in vitro* fertilization in which the sperm of the patient's husband is used to fertilize the donor eggs. The fertilized embryo is then transferred to the patient, who has been appropriately treated with exogenous estrogen and progesterone synchronized to mimic the normal ovulatory cycle.

Female Reproductive Tract Disorders

The primary treatment of outflow tract disorders is surgical – the incision of labial fusion, imperforate hymen, and vaginal septum, which leads to the return of regular menstrual periods and fertility. With respect to specific disorders, chronic labial adhesions in children can be treated with intermittent estrogen cream; however, a functional vagina in women with Müllerian agenesis or testicular feminization is more difficult to achieve. First, an attempt at nonsurgical dilation of a blind-ending vaginal pouch or perineal dimple is indicated. If this fails, a reconstruction of the vagina using skin grafts is performed. Disorders of cervical obstruction can be treated by the dilation of the cervix, and pregnancy can be achieved by intrauterine insemination. If the cervix is absent, however, the treatment usually requires a hysterectomy because the retained blood behind the obstruction can cause significant pain and infection. Uterine scarring or Asherman's syndrome is best treated by the direct hysteroscopic resection of the adhesions.

Semantic memory

Our general knowledge about the world, such as information about words and their meanings, facts, concepts, objects, and people; typically retrieved without recollection of where and when the information was initially acquired.

Temporal lobe

The area of the brain generally considered the permanent store of our episodic and semantic memories, part of the neocortex.

Organic Amnesia**Stress-Related and Transient Amnesic States****Glossary****Episodic memory**

The store of personally experienced events from the past, including details of the content of the episode and also of its context — when and where it occurred.

Frontal lobe

The brain area thought to play a role in the strategic control of memory processes necessary for complex recollective memory functions.

Hippocampal complex

Structures located in the medial temporal lobe of the human brain (e.g., the hippocampus, subiculum, parahippocampal gyrus, and entorhinal cortex); implicated in the learning and at least the temporary storage of recent memories.

The term amnesia refers to a partial or total loss of memory that can result from organic brain damage and/or some forms of psychological stress. The loss of memory can affect events or experiences that occur subsequent to the onset of the disorder (anterograde amnesia) or those that took place prior to its appearance (retrograde amnesia). Furthermore, although amnesia most often occurs for personal autobiographical events (episodic memory), some patients also show a loss of their factual knowledge about the world (semantic memory).

Organic Amnesia

The most well-studied case of organic amnesia in the literature is that of HM, who became amnesic in his mid-twenties after an operation to relieve the symptoms of severe epilepsy. HM's operation involved surgery to the hippocampal complex and parts of the temporal lobe in both brain hemispheres. Although

HMs epilepsy improved following surgery, he became profoundly amnesic, unable to remember events just after they had happened and many that had occurred prior to his operation. For example, he was severely impaired at recalling lists of words that had just been read to him and at recognizing those words as the ones he had heard before when they were presented to him again. This was also the case when he was asked to remember other types of stimuli, such as faces, numbers, sounds, or shapes. There are now over 50 reported patients who, like HM, show difficulties with learning after damage to the hippocampal complex. This region in the human brain is, therefore, considered critical for the acquisition of new episodic and semantic memories.

As well as being unable to remember events from moment to moment, patients with damage similar to HM often have difficulty remembering events that occurred a number of years previously. This pattern of memory loss, in which memories from the distant past (e.g., childhood or early adulthood) are typically remembered better than more recently experienced events (e.g., from the day, week, or year before), is a phenomenon that has fascinated memory researchers for over 100 years. The fact that memory loss can be so dramatically affected by the age of the memory has led some researchers to conclude that the system involved in acquiring new human memories, the hippocampal complex, may not necessarily be involved in the permanent storage of all our episodic and semantic memories. Instead, other areas of the brain, such as the anterior temporal lobes, may be the location for our enduring stores of human memory, especially semantic knowledge about the world. Studies of patients with damage that affects the temporal neocortex, but less so the hippocampal complex, highlight the complementary roles played by these regions in long-term memory. These patients often show the opposite pattern of memory impairment to HM and other patients with damage to the hippocampal complex, that is, better recall of recent memories than those from childhood or early adulthood. Although it is currently unclear how the different temporal-lobe regions interact in the acquisition and storage of episodic and semantic memory and whether the effects of memory age evident in patients reflect a true transfer of information between brain structures, most current theories of memory concur that memory consolidation, perhaps occurring during sleep, is a critical aspect of memory storage.

In recent years, the important role in memory played by another brain area, the frontal lobe, has become clearer. Patients with specific damage to this region often exhibit symptoms of impulsiveness and lack of inhibition that affect personality and behavior,

but careful testing can reveal impairments in certain aspects of memory function. For example, such patients often have difficulty remembering details of the context in which previous events were experienced, such as where or when the event occurred. Moreover, they are typically impaired, like patients with hippocampal complex damage such as HM, at recalling lists of words that were previously presented. In contrast to hippocampal complex dysfunction, however, frontal lobe damage may spare the ability to recognize information as having been seen before. Such evidence suggests that the frontal lobe and hippocampal complex work together to perform relatively complex, effortful memory tasks such as recalling words, that require the strategic search of the memory store, as well as organization and manipulation of retrieved material. The idea that interactions between the frontal and temporal lobe areas are important for memory function is supported by data from a patient with damage to the uncinate fascicle, a bundle of fibers that provides an important connection between these brain regions. This patient was impaired at recalling autobiographical events from his past, but performed normally at recognizing and discriminating events that he had experienced from those he had not.

Stress-Related and Transient Amnesic States

In addition to instances of organic amnesia, psychological stresses can result in impairments to and distortions of memory. One of the main types of nonorganic memory loss occurs as part of the syndrome termed posttraumatic stress disorder and in many circumstances can be linked to the experience of a precipitating traumatic event such as a natural disaster, accident, or war. The phenomenon was first recognized during World War I, when soldiers returned from the front affected by shell shock, characterized by recurring nightmares and flashbacks to their traumatic experiences. The disorder can also manifest as the loss of one's identity and of autobiographical memories from around the time of the precipitating event, referred to as psychogenic or dissociative amnesia. For example, studies of soldiers conducted following World War II suggested that up to 5% had no memory for the traumatic combat events they had recently experienced.

One possible explanation for these types of amnesia may be that they reflect a psychological defense mechanism that attempts to repress or inhibit retrieval of the traumatic memory and prevent it from reaching conscious awareness. Evidence suggests that such retrieval inhibition processes are supported by regions in the frontal lobes, emphasizing the important role

for this brain area in memory. Stress-related forgetting may be transient in nature, and patients can sometimes recover their memories after the appropriate treatment or therapy. The recovery of traumatic memories following therapy has proven controversial, however, with some commentators questioning the accuracy of such recovered recollections and suggesting that the techniques sometimes used in therapy sessions might lead patients to remember false traumatic events (ones that had not in fact previously occurred). This debate remains largely unresolved, with evidence suggesting that retrieval inhibition processes do certainly exist but, at the same time, that one's memory of past events can be highly susceptible to suggestibility biases and distortions at the time of recall.

Although one of the diagnostic criteria for psychogenic amnesia is that there is no evidence of structural brain damage, the increasing use of sophisticated neuroimaging techniques that measure levels of blood flow in the brain suggest that there can be altered brain function in some cases, although the reasons for this are currently unclear. For example, one study examined brain activity in a patient with a persistent psychogenic amnesia for the whole of his past life. When the patient was thinking about his autobiographical memories, blood flow was found to be greater in the same brain regions that control subjects engaged during the processing of nonpersonal memories. This suggests that some patients with psychogenic amnesia may treat previously personally salient episodic memories in a neutral, semantic way, as if they no longer belonged to them, perhaps in order to escape the emotional associations of the traumatic episode(s) that triggered the amnesia. Alternatively, it is possible that the brain regions typically involved in processing autobiographical recollections, which are similar to those involved in processing emotional information, may be temporarily disrupted as a result of experiencing the stressful event, leaving the brain

regions used for processing neutral memories as the only means by which autobiographical memories can be processed.

The important link between stress and memory can be further revealed in a syndrome called transient global amnesia (TGA). Although not classified as a psychogenic amnesia (patients are rarely confused about their own identity), the disorder is characterized by abrupt confusion and a complete anterograde amnesia, which eventually shrinks after (typically) 4–6 hours. Although there are known risk factors for TGA, such as a history of epilepsy or migraine, in as many as 30% of cases attacks can be directly linked to precipitating stresses, such as strenuous exertion, pain, immersion in water, and emotional events. Recent neuroimaging studies have revealed physiological changes (low blood flow) in the hippocampal complex during an attack. It is possible, therefore, that extreme stress may result in memory impairment because the hippocampal complex is part of a complicated network in the human brain that mediates fear-related behavior and stress responses, as well as aspects of memory function. Highly stressful situations may overstimulate the hippocampus and related structures, leading to decreased blood flow in this region of the brain and subsequent memory loss.

Introduction

Multiple Sources of Input: Afferents to Amygdala

Variegated Outputs: Efferents from Amygdala

Conclusions and Functions

Glossary

<i>Central nucleus of the amygdala (CeA)</i>	This striatal-like nucleus is considered the motor interface of the amygdala.
<i>Lateral amygdala (LA) and basolateral amygdala (BLA)</i>	These cortical-like structures are considered the sensory interface for the amygdala's role in fear, anxiety, and stress.
<i>Long-term potentiation (LTP)</i>	A relatively long-lasting form of synaptic plasticity that has been proposed as a mechanism that mediates some forms of learning and memory
<i>Pavlovian fear conditioning</i>	A learning paradigm in which an aversive event is paired with neutral stimuli, resulting in a variety of defensive behavioral and autonomic conditional responses to the previously neutral stimulus. It is the natural way that defensive behavior is controlled but can also contribute to anxiety disorders. In the laboratory it has become a standard way to assess learning and memory.

Introduction

The amygdala, an almond-shaped cluster of interconnected nuclei in the medial temporal lobe, may be the neural structure most intimately tied to emotion. It has long been known that damage to the amygdala produces disturbances in emotional behavior. The linkage is particularly compelling in the case of negative emotions such as fear. In both human and nonhuman animals, fear-related behavior, which is typically analyzed with Pavlovian fear conditioning, depends on the amygdala. Humans with bilateral amygdala damage have difficulty in recognizing the

negative emotions in the facial expression of others and as a result may make inappropriate social advances. Rats with lesions of the amygdala lose their fear of cats. Additionally, the ability of emotion to influence declarative memory storage (flash bulb memories) is mediated by the amygdala. The amygdala is well situated for a role in stress and emotion. Features of the environment, initially processed by several different brain regions, converge on the amygdala. Much of this information relates to external and internal stress. Plasticity within certain nuclei of the amygdala allows this structure to connect these stressors with environmental features that predict stress. Therefore, it may also act as a feedforward device that generates behavior in anticipation of stress. This article first reviews the major afferents to the amygdala that bring it this environmental information. Then it turns to the efferents that project to the brain regions that generate behavioral responses to stress. It concludes with a description of the processing that goes on within the amygdala that enables this feedforward regulation of stress.

Multiple Sources of Input: Afferents to Amygdala

Nucleus Tractus Solitarius

The nucleus tractus solitarius (NTS) projects to the amygdala's central nucleus (CeA), both directly and indirectly, via the parabrachial nucleus. A large body of evidence implicates the NTS in stress-related responses. It receives first-order projections from several cranial nerves, including the vagus. These inputs primarily reflect the contribution of visceral sensory information but also convey general somatic input. In addition, ascending pain-related fibers originating from the spinal cord terminate in the NTS. Thus, the NTS can provide the amygdala with visceral sensory, somatosensory, and pain-related information.

Thalamus

The amygdala receives a wide range of sensory information via monosynaptic projections from the thalamus. Considerable functional importance has been attributed to projections from the posterior thalamus to the amygdala. The moderate projection from the paraventricular nucleus terminates in the medial and ventrolateral divisions of the lateral amygdala (LA). Those arising from the medial geniculate provide the LA with auditory information. Pain information

represented in the posterior intralaminar nucleus of the thalamus also project to several amygdaloid nuclei. Stimulation of these posterior thalamic projections to the LA can support Pavlovian fear conditioning to an auditory cue. Somatosensory regions of the thalamus are an important route of unconditional stimulus transmission to the amygdala in fear conditioning. However, information about the unconditional somatosensory stimulus is also transmitted from other sources that send fibers through (but do not form essential synapses in) the thalamus en route to the amygdala. The CeA may receive direct thalamic inputs about the conditional stimulus as well as nociceptive stimuli. Furthermore, parts of the ventro-posterior medial thalamic nucleus that primarily receive visceral and gustatory information project to the amygdala. These projections may support the amygdala's role in avoidance of novel flavors. In summary, the thalamus is a significant and direct source of information about the internal and external milieu for the amygdala.

Periaqueductal Gray

The midbrain periaqueductal gray (PAG) is the key structure for integrated defensive behavior. While much emphasis has been placed on descending projections from the amygdala to PAG (see later), these projections are largely reciprocal. There are strong projections from PAG to amygdala, particularly to the CeA. In certain situations, lesions of the dorso-lateral PAG will enhance conditional fear responses that depend on the amygdala. This has led to the suggestion that the ascending projections from the dorsolateral PAG may exert an inhibitory influence on the amygdala.

Temporal, Insular, and Parietal Cortex

There is a massive exchange of information between the amygdala and the cortex. Along with the sensory projections from the thalamus, the amygdala receives both modality-specific and multimodal neocortical projections. Unimodal projections coding aspects of visual, auditory, and somatosensory information project primarily to the LA and the basolateral nucleus (BLA). Importantly, these projections tend not to originate from the primary sensory cortex. Rather, unimodal sensory information originates from secondary sensory regions. For example, auditory projections arise from Te2 and Te3, and visual information arrives through the perirhinal cortex. The insular cortex, which receives monosynaptic projections from the primary somatosensory cortex, sends substantial projections to both the BLA and LA. It has been suggested that these projections provide the amygdala

with nociceptive information that can support fear conditioning.

The hippocampal formation receives some of the most highly preprocessed information in the brain. This component of the temporal cortex projects to the amygdala via sparse projections from the entorhinal cortex, CA1, and subiculum. Fibers from the entorhinal cortex and subiculum pass through the ventral angular bundle, and electrical stimulation of this tract results in a monosynaptic response in the BLA. These projections seem to play an important role in providing contextual or place information for amygdala-dependent behaviors, as lesions of this tract produce deficits in contextual fear conditioning. At least as far as simple emotion-related behaviors are concerned, the thalamo-amygdala and cortico-amygdala circuits appear to have some redundant function and act compensatorily because damage in both pathways appears necessary to eliminate amygdala-dependent behaviors. It is possible that the cortical pathways may allow amygdala-dependent stress responses to be more finely contoured to the specifics of environmental stimulation, but such an analysis has not been performed.

Frontal Cortex

The infralimbic (IL) region of the medial prefrontal cortex strongly projects to the intercalated cells in the amygdala. In turn, intercalated cells project to the CeA. Lesions of IL impair extinction, and electrical stimulation of IL reduces the expression of conditional fear. Therefore, it has been proposed that insufficient inhibition of the amygdala by the medial prefrontal cortex could predispose an individual to develop anxiety disorders. Thus, in terms of cortical information, the amygdala predominately receives highly processed sensory representations that likely play important roles in the coordination of appropriate behavioral responses.

Summary

A diverse array of neural pathways brings the amygdala a wide range of environmental information. Inputs from various functional systems terminate in certain amygdaloid nuclei, and, therefore, different nuclear divisions are exposed to different sets of information. Note that the same divisions might receive inputs from various sources. These interdivisional projections provide a route by which the various kinds of information entering the different portions of amygdala can be associated. In addition to convergence, parallel distribution of information from the same source to multiple amygdaloid areas is another typical feature in the organization of amygdaloid

inputs. Most of this sensory information has been highly processed before it arrives at the amygdala. This suggests that the amygdala may provide an information-integrating function in the regulation of stress.

Variegated Outputs: Efferents from Amygdala

In addition to providing reciprocal projections to many of the sensory regions from which it receives input, the amygdala also sends efferent projections to regions responsible for behavioral, autonomic, and endocrine responses to stress. These outputs are organized in a point-to-point manner. It also provides parallel outputs to multifunctional systems, and there are also parallel outputs from various amygdaloid nuclei to the same functional system. These anatomical relationships allow amygdala activity to influence the unconditional response to stress and also to provide substrates by which stimuli predictive of impending stressors can produce anticipatory behavioral adjustments.

Hypothalamus

Physical stress produces a variety of neuroendocrine responses, including increases in plasma adrenocorticotropin (ACTH), corticosterone, norepinephrine, and epinephrine. Control of these responses is mediated in part by a direct action of the hypothalamic paraventricular nucleus on pituitary secretion. The paraventricular hypothalamus has been shown to receive direct projections from the CeA, providing a pathway by which amygdala activity can contribute to endocrine stress responses. A variety of studies have demonstrated a role for the amygdala in the expression of neuroendocrine responses to stress. Lesions of the amygdala attenuate the elevation of plasma epinephrine, norepinephrine, and corticosterone normally observed following footshock, and similarly attenuate the elevation of plasma ACTH produced by immobilization stress but do not completely block these responses. However, given that amygdala lesions do not completely block or alter baseline hormone levels, it is possible that the amygdala lesion-induced attenuation of hormone responses reflects disruption of feedforward amygdala-dependent conditional responses rather than an amygdala control of unconditional endocrine responses.

Projections from the LA and the BLA to the hypothalamus are light and target the lateral hypothalamic area. However, the CeA provides substantial inputs to a larger number of hypothalamic nuclei. Most of the projections originate in the medial division.

Moderate to heavy projections are directed to the medial and lateral preoptic area, lateral hypothalamus, and paraventricular nucleus. Lesions of both the CeA of the amygdala and the lateral hypothalamus block the increase in arterial blood pressure caused by a conditional fear stimulus, leading to the suggestion that projections from the amygdala to the lateral hypothalamus mediate this response. Importantly, the hypertension to the shock unconditional response remains intact following hypothalamic lesions. In addition to these direct projections to the hypothalamus, the CeA has strong projections to the bed nuclei of the stria terminalis, which also innervates hypothalamic nuclei. Thus, the lateral hypothalamus seems to mediate conditional sympathetic autonomic arousal to fear stimuli via input from the CeA.

Periaqueductal Gray

The CeA projects heavily to the caudal half of the midbrain PAG. These projections initially innervate more dorsal regions of the PAG, areas that serve active or circa strike defensive behaviors and autonomic arousal. Stimulation of the medial and central amygdala inhibits the behaviors that are generated by stimulation of these dorsal regions of the PAG.

As one moves caudally in the PAG, the CeA projections gradually rotate to innervate the ventral portions of the PAG. These ventral PAG areas are essential for conditional fear-related defenses such as freezing. This area is also critical for the opioid analgesia that accompanies fear. Consistent with this pattern, cells in the caudal ventral PAG express *c-fos* following fear conditioning. However, this part of the PAG is not critical for the autonomic responses to conditional fear stimuli. The amygdala, predominantly through projection emanating from the CeA, exerts control over species-specific defensive behaviors organized by the PAG.

Brain Stem

The CeA sends projections throughout the brain stem. One function of these projections is to provide control over autonomic function. For example, stimulation of the rabbit's CeA causes a heart rate deceleration mediated by monosynaptic projections to the dorsal motor nucleus of the vagus. This response mimics the bradycardia rabbits show to conditional fear stimuli, which also depends on the CeA. While amygdala lesions block the bradycardiac conditional response to the stimulus paired with electric shock, it is important to note that these lesions do not affect baseline heart rate or the unconditional heart rate orienting response to the conditional stimulus in rabbits. Thus, projections from the CeA to brain stem

autonomic nuclei may mediate parasympathetically controlled conditional responses.

Amygdala stimulation enhances reflexes organized in the brain stem such as eyeblink and startle. There are both mono- and disynaptic projections from the CeA to the nucleus reticularis pontis caudalis, which is the part of the brain stem acoustic startle circuit that is modulated by conditional fear stimuli. It has previously been shown in rats, cats, rabbits, and monkeys, using various anterograde tracers, that CeA neurons project to brain stem areas including the NTS. These results provide conclusive evidence for a GABAergic pathway from the CeA to the NTS. Although lesions of the amygdala block the ability of fear stimuli to modulate reflexes, it is important to note that the reflex itself is left intact.

Thus, projections from the CeA to several brain stem regions allow for widespread modulation of autonomic function and reflexive behaviors.

Cortex

In addition to the amygdala receiving substantial cortical projections, recent work suggests that it is in a position to exert widespread influence over cortical activity. Based on anterograde tracer studies, the LA provides strong, topographically organized inputs to the ventral and dorsal perirhinal cortices. The LA also provides a moderate input to the infralimbic cortex as well as to the ventral agranular insula. Projections from the BLA to the frontal cortex are more widespread than those from any other amygdaloid nucleus. The CeA sends substantial ascending projections to the cholinergic basal forebrain, which in turn projects diffusely to virtually all cortical regions. Basal forebrain stimulations produce desynchronization of cortical EEG, as does CeA stimulation. Basal forebrain stimulation supports associative changes in receptive field properties of auditory cortical neurons. Based on these findings, it has been suggested that cholinergic modulation of cortical activity, mediated by amygdala projections to the basal forebrain, is critical for the induction of the stimulus-specific changes in cortical receptive fields observed during Pavlovian fear conditioning.

Hippocampal Formation

In addition to modulating cortical dynamics, the amygdala also exerts a strong influence over hippocampal activity. The hippocampus is considered to be particularly susceptible to chronic stress because it is heavily enriched with corticosteroid receptors and it participates in the termination of stress responses via the glucocorticoid-mediated negative feedback of the

hypothalamus-pituitary-adrenocortical (HPA) axis. Because this medial temporal lobe structure is crucial for declarative-explicit memory in humans and spatial-relational memory in rodents, evidence is emerging that stress generally impairs hippocampal-dependent memory tasks in both humans and rats. Lesions of the BLA attenuate the induction of long-term potentiation (LTP) in the dentate gyrus, while BLA stimulation significantly facilitates LTP induction. Recent findings indicate that amygdalar activity is crucially involved in the emergence of stress-induced impairments in hippocampal LTP and hippocampal-dependent spatial memory in rats. The critical period of the amygdalar contribution to stress effects on hippocampal functions was determined by applying muscimol either before or immediately after stress. Results indicate that intra-amygdalar muscimol infusions before restraint tailshock stress effectively blocked stress-induced physiological and behavioral effects. Thus, the amygdala plays a critical role in the induction of cortical- and hippocampal-dependent processes thought to underlie learning and memory.

Summary

The CeA, which receives input from most of the amygdala nuclei, projects to regions responsible for autonomic, hormonal, and behavioral responses. In this way, the amygdala is in a position to muster the full arsenal of the body's responses to stress.

Conclusions and Functions

There are numerous brain structures that are essential components of the neural circuitry mediating stress responses. The amygdala is one of the neural hubs integrating these components and stands in a position to both influence and be influenced by the stress response. Animal models of chronic stress reveal that stress-induced structural plasticity in amygdala neurons provides a candidate cellular substrate for affective disorders.

The amygdala receives a plethora of sensory input from both the environment and the body. Much of this input relates to stressful and threatening events. However, the amygdala also receives both simple and highly processed sensory information that can serve a signaling function. This suggests that the amygdala may integrate these sources of information. An early suggestion was that the amygdala recognizes signals for events with emotional significance. This is perhaps most clear in fear conditioning, in which cues that predict an event come to produce a number of fear-related responses. These behaviors are lost in rats, mice, rabbits, and humans, without an

amygdala. There is an LTP of amygdala responses to stimulation of its thalamic, hippocampal, and cortical afferents. Cells in the LA receive both nociceptive somatosensory information and auditory information, and exposure to fear conditioning itself can potentiate the response of these cells. In this manner, stimuli that predict stress can come to activate the amygdala, even if they are not stressful in their own right. Thus, neural plasticity within the amygdala provides the ability for this structure to anticipate stress through learning processes such as Pavlovian fear conditioning. Consistent with such a view, the amygdala projects to most of the brain areas responsible for rapid coping with impending danger.

Under circumstances in which prolonged stress disrupts cognition that is mediated by the hippocampus, it facilitates amygdala-dependent cognition. More specifically, under circumstances in which chronic stress induces dendritic atrophy and debranching in CA3 pyramidal neurons of the hippocampus, it induces hypertrophy of pyramidal and stellate neurons in the LA, the BLA, and the bed nucleus of stria terminalis, an amygdaloid projection site central to anxiety. Chronic unpredictable stress, however, had little effect on pyramidal and stellate neurons and induced atrophy only in BLA bipolar neurons. Thus, stress hormones released as a result of stress-induced amygdala activity can strengthen the excitatory drive within the BLA and thereby influence subsequent information processing by the amygdala and its downstream targets. This suggests that chronic stress could lead to an imbalance in HPA axis function through a gradual gain in excitatory control exerted by the amygdala. In this way, a system that evolved to deal with immediate threats of great evolutionary urgency also has the ability to cause debilitating pathology. The amygdala allows organisms to better cope with future stress by modulating cortical, hippocampal, and striatal circuits involved in declarative memory and motor learning. Through such anticipatory mechanisms, the amygdala provides for the adaptive feedforward regulation of stress. But the amygdala's powerful and adaptive role in short-term emergencies may also leave it open to a role in pathology accompanying chronic stress.

Introduction

Hypothalamus: The Neuroendocrine Paraventricular Nucleus

Neurohypophysis: Median Eminence and Infundibular Stalk

Adenohypophysis: Corticotropes in the Pars Distalis

Adrenal Cortex: Zona Fasciculata

Glossary

<i>Acidophils</i>	Cells that stain with acidic (anionic) histochemical stains.
<i>Basophils</i>	Cells that stain with basic (cationic) histochemical stains.
<i>Chromophobes</i>	Cells that do not stain with either acidic or basic histochemical stains.
<i>Fenestrated capillary</i>	A specialized capillary that has transcellular circular openings in the endothelial walls allowing the passage of large molecules or cells in or out of the capillary. They are particularly prevalent in regions where secretory products are released into the vasculature.
<i>Magnocellular neurons</i>	Neurons of relatively large size.
<i>Mesoderm</i>	A principal layer of the mammalian embryo from which derives the vascular tissue.
<i>Neuroectoderm</i>	A principal layer of the mammalian embryo from which derives the nervous tissue.
<i>Parvicellular neurons</i>	Neurons of relatively small size.
<i>Telencephalon</i>	The part of the forebrain containing the cortical regions, basal ganglia, amygdala, and septal nuclei.

Introduction

The hypothalamic-pituitary-adrenal (HPA) axis is a critical endocrine system that contributes to the maintenance of the daily energy balance and forms a fundamental part of the endocrine stress response. It consists of three serially arranged elements connected by vascular links, whose final motor output depends

largely on a feed-forward sequence of humorally directed chemical signals: neuroendocrine (corticotropin releasing hormone, CRH; and in some species arginine vasopressin, AVP) originating from a specific set of neuroendocrine neurons in the hypothalamic paraventricular nucleus (PVN), endocrine (adrenocorticotrophic hormone, ACTH, released from the anterior pituitary corticotropes), and adrenal glucocorticoid (generally cortisol or corticosterone, depending on the species). The impact of various neural and humoral inputs on each of these three elements allows for a complex array of interacting regulatory influences including afferent neural control in the brain, a variety of circulating hormones, and local paracrine interactions within the anterior pituitary and adrenal cortex.

Hypothalamus: The Neuroendocrine Paraventricular Nucleus

Location

The hypothalamic paraventricular nucleus (PVN) is a heterogenous collection of neurons that constitutes one of the principal motor output systems of the hypothalamus. It is a bilateral structure located either side of the third ventricle and is an elaboration of the periventricular zone of the hypothalamus. One set of PVN neurons provides extensive projections to the hindbrain and spinal cord and regulates behavioral and autonomic motor activity. The other set is neuroendocrine in nature and has terminals in the neurohypophysis. In turn, these neuroendocrine neurons can be further divided into two groups. The first are magnocellular and are found in the PVN and supra-optic nuclei. They have terminals in the infundibular process (or neural lobe) and release either AVP (or vasotocin in nonmammalian groups) or oxytocin into the general vasculature. The second are parvicellular and are generally located (at least in the rat) more medially than the magnocellular neuroendocrine neurons in the PVN. They have terminals in the median eminence (ME) and release release-regulating hormones into the hypophyseal portal vasculature to regulate anterior pituitary function.

Subdivisions

The various subdivisions of the PVN of most species are not easily differentiated into discernible cytoarchitectonic compartments. However, in the rat (in which much of the work on neural compartmentalization

has been performed) it is possible to delineate approximately 10 separate subdivisions. Of these, the dorsal aspect of the medial parvicellular (mpd) part contains the CRH neuroendocrine neurons responsible for generating the adrenocortical stress response. CRH stimulates the release of ACTH both *in vivo* and *in vitro*, and lesions of the PVN or its projections to the ME have convincingly demonstrated that these cells are the source of CRH secreted into the hypophyseal portal vasculature.

Corticotropin Releasing Hormone Neuroendocrine Motor Neurons

In the rat, there are approximately 2000 CRH neurons on each side of the PVNmpd (Figure 1a). The cell bodies of these neurons are typically fusiform and are approximately 10 μm in diameter. They have a rather simple dendritic arbor, usually consisting of two, sometimes three, relatively thick dendrites located in a bipolar arrangement (Figure 1b). These dendrites are significantly shorter than those found on neurons with descending projections. The dendrites of CRH neurons generally remain within the nucleus, but in some instances they extend into the magnocellular parts of the PVN. Their axons emerge laterally from the PVN (Figure 1a), eventually curving around the dorsal aspect of the fornix, before turning ventrally and then caudally to terminate in the portal capillary plexus located in the external zone of the ME.

In many species, AVP is also an important regulator of ACTH secretion and is released into the hypophyseal portal vasculature. In the rat, AVP is synthesized in approximately half of the neuroendocrine CRH neurons in the PVN, which are generally more numerous in the dorsal part of the PVNmpd. AVP appears to play a key role in modulating the actions of CRH on anterior pituitary corticotropes, although the extent of its contribution varies among species. Parvicellular AVP is exquisitely sensitive to corticosterone feedback and is copackaged with CRH in dense core vesicles, but it is regulated differentially from CRH by glucocorticoids and a variety of stressors. Although a number of studies have attempted to show that AVP from axons originating in magnocellular cells contribute to ACTH secretagogue release in the external layer of the ME, the precise contribution of this magnocellular system to the regulation of ACTH still remains to be clarified.

Afferent Input

Coordinating the activity of CRH neurons in the PVNmpd in response to stress depends on sets of afferent inputs from many regions of the brain. In general, these inputs can be divided into two groups:

Figure 1 Paraventricular nucleus (PVN) of an adrenalectomized rat and CRH. a, Low-power photomicrograph of PVN stained immunohistochemically for CRH; b, high-power photomicrograph of PVN neuroendocrine CRH neurons. In a, note the densely stained neurons in the medial parvicellular part of the PVN and their axons exiting the nucleus in a lateral direction. The medially located third ventricle is to the right. In b, note the characteristic fusiform cell bodies (white arrowheads) with large unstained nuclei, and the generally bipolar location of the dendrites. Photomicrographs from the author's laboratory.

those that target PVNmpd neurons directly and those that are channeled through intermediate regions such as the bed nuclei of the stria terminalis (BST) and peri-PVN regions.

Many of the inputs that directly target CRH neurons originate from the hindbrain, some regions of the hypothalamus, and circumventricular organs in the forebrain. Direct catecholaminergic inputs into the PVN from the hindbrain travel in the ventral noradrenergic bundle and play a particularly prominent role in conveying visceral sensory information to neuroendocrine neurons. Noradrenergic innervation to the parvicellular neuroendocrine PVN originates predominantly from the A2 cell group in the medial and commissural divisions of the nucleus of the solitary tract. The A2 cell group receives first-order vagal and glossopharyngeal afferents and therefore can also relay visceral sensory information to the PVN. A minor contribution arises from the A1 and A6

(locus ceruleus) cell groups. Most of the adrenergic fibers (which also contain neuropeptide Y, NPY) arise in the C1 cell groups. The hypothalamic cell groups that project directly into the PVNmpd include the dorsomedial nucleus, some preoptic nuclei, and some peri-PVN regions. The neurochemical nature of these projections is still under investigation, but both γ -aminobutyric acid (GABA) and glutamate are likely to be important transmitters in these projections.

The subfornical organ (SFO) and vascular organ of the lamina terminalis (OVLT) are circumventricular organs that lack a blood–brain barrier and can provide an entry point for humoral factors that are ordinarily excluded from the central nervous system (CNS). Both of these midline structures are located in the forebrain and provide efferent projections directly into the PVN. They are thought to be particularly important for mediating the HPA response to increased circulating angiotensin II (particularly the SFO) and increases in vascular osmolality (the OVLT). In addition, direct projections from a third cell group in the rostral hypothalamus, the median preoptic nucleus, may also contribute in this function.

Information from telencephalic regions, including the amygdala, hippocampus, and lateral septal nuclei, probably play an prominent role in mediating the more cognitive influences on the activity of the HPA axis. However, these particular regions do not provide direct projections into the PVN, and their impact on neuroendocrine CRH neurons and ACTH secretion are thought to be channeled more through projections from a variety of nuclei in the BST. There is evidence that GABA plays an important role in this function.

Neurohypophysis: Median Eminence and Infundibular Stalk

The defining feature of neuroendocrine neurons is that they release their chemical signals into fenestrated capillaries in the neurohypophysis rather than into the characteristic synaptic cleft found in neuron-to-neuron transmission. Once in the vasculature, these signals are then carried to their targets by the blood flow and act on targets that are effectively defined by the presence of specific receptors.

Structure

The neurohypophysis is a midline structure that derives from an outgrowth from the floor of the hypothalamus. It consists of the ME, the infundibular stalk, and the infundibular process (the neural lobe or pars nervosa) of the pituitary gland (**Figure 2**). Of these structures, the ME and infundibular stalk

are critical parts of the HPA axis. The ME is where axons from neuroendocrine CRH neurons in the PVNmpd have their terminals adjacent to the primary capillaries of hypophysial portal system. It is a highly complex structure consisting of a looped network of fenestrated capillaries, axon terminals, and tanyocytes, which are specialized ependymal cells that have processes extending from the third ventricle to the axon terminals on the capillary plexus. In the case of the CRH neurons that regulate anterior pituitary corticotrope function, secretagogues are released in an activity-dependent manner into the blood flowing through the hypophysial portal vasculature toward the pituitary gland from neuroendocrine terminals in the ME.

Organization of Blood Supply

The organization of the blood supply to the rat pituitary gland is shown in **Figure 3**. The arterial blood supply of the ME and infundibular stalk arises from the internal carotid artery and the circle of Willis, and it flows into the capillary bed of the ME from branches of the anterior hypophysial artery. These vessels form extensive capillary loops in the external part of the ME close to the terminals of the CRH neuroendocrine motor neurons. As they leave the ME, these capillaries drain into the long portal vessels

Figure 3 The pituitary gland of the rat showing the main features of the blood supply to its ventral aspect. AC, anterior cerebral artery; AH, anterior hypophyseal artery; B, basilar artery; IC, internal carotid artery; LPV, long portal vessel; ME, median eminence; OC, optic chiasm; P, peduncular artery; PC, posterior communicating artery; PD, pars distalis; PH, posterior hypophyseal artery; S, pituitary stalk. that lie parallel in the infundibular stalk and then course into the pars distalis. On entering the pars distalis, the long portal vessels anastomose, allowing the release-regulating hormones access to its secretory cells. A second capillary bed is found closer the pituitary gland. It is supplied by blood from the artery of the trabecula and produces the short portal vessels, which then enter the pars distalis in parallel to the long portal vessels.

Adenohypophysis: Corticotropes in the Pars Distalis

The adenohypophysis is nonneural tissue that develops from an ectodermal evagination of the roof of the buccal cavity, Rathke's pouch. It has three parts: pars distalis, tuberalis, and intermedia. The pars tuberalis makes up approximately 75% of the adenohypophysis (Figure 2) and contains the corticotropes that synthesize ACTH from its precursor proopiomelanocortin (POMC). Pars distalis cells are arranged in cords or clusters interspersed between capillaries

from the hypophyseal portal vessels. Corticotropes are separated from one another by thin-walled vascular sinusoids and are supported by a skeleton of reticular tissue. Classically, cells of the pars distalis have been characterized into three groups based on their stainability: acidophils, basophils, and chromophobes. Although these categories are not as clear cut as was originally thought, corticotropes are basophilic and show strong periodic acid Schiff (PAS) staining. CRH and AVP released into the hypophyseal portal vasculature eventually bathe corticotropes and stimulate the synthesis and secretion of ACTH. In terms of their response to these secretagogues, there appears to be three type of corticotropes: those responsive to CRH and not AVP; those responsive to CRH or AVP; and those responsive to CRH and AVP. Thus, changes in the CRH/AVP ratio could affect the overall ACTH secretory pattern.

Adrenal Cortex: Zona Fasciculata

Structure

The mammalian adrenal glands are bilateral structures located in perirenal adipose tissue found dorsal to the kidney. They each consist of cortical steroid-synthesizing tissue derived from the mesoderm and medullary catecholamine-synthesizing tissue derived from the neuroectoderm (Figure 4). The thin outermost part of the adrenal cortex, the zona glomerulosa, is the main site of mineralocorticoid production. Glucocorticoids (either cortisol or corticosterone) are primarily produced by the zona fasciculata in response to circulating ACTH (Figure 4), and this constitutes the largest amount of steroid-synthesizing tissue in the adrenal gland. The androgens dehydroepiandrosterone and androstenedione are produced in the innermost zona reticularis. The zona fasciculata consists of long thin cords, each of one or two cells separated by parallel fenestrated venous capillaries. These cells are approximately 20 μm in diameter and contain the large amounts of smooth endoplasmic reticulum, mitochondria, and lipid droplets characteristic of steroid-synthesizing cells. They also possess reasonable amounts of rough endoplasmic reticulum, as well as greater numbers of gap junctions than are found between zona glomerulosa cells.

Blood Supply

The blood supply to the adrenal cortex is ultimately derived from three groups of arteries: the superior (arising from the inferior phrenic artery), the middle (arising from the aorta), and the inferior (arising from the renal artery or aorta) adrenal arteries. These arteries then branch to form a plexus in the adrenal

Figure 4 Sections through the adrenal glands of rats. a, Normal rat; b, hypophysectomized rat. Because the functional capacity of the adrenal cortex is maintained by circulating ACTH, hypophysectomy results in tremendous shrinkage of the cortex. The medulla (catecholamine-synthesizing tissue) is not affected by hypophysectomy. Both sections are drawn to scale. Adapted from Turner, C. D. and Bagnara, J. T. (1976), *General endocrinology*, Philadelphia: W. B. Saunders.

capsule (which constitutes the outside of the gland), from which arises the cortical arteries supplying the three layers of the adrenal cortex. Venous outflow from the cortex enters a number of sinuses in the adrenal medulla and eventually join the adrenal vein. In the human, the left adrenal vein joins the renal vein and the right adrenal vein enters the vena cava.

Innervation

The mammalian adrenal cortex is innervated by postganglionic sympathetic fibers in the greater and lesser splanchnic nerves originating in thoracic regions T8 to T11 of the vertebral column. This postganglionic innervation is most likely derived from pre- and para-vertebral ganglia, including the suprarenal ganglion.

Moreover, the cortex also receives input from adrenal medullary ganglion cells, emphasizing the complexity of the local regulation that can occur within the adrenal gland. Nerve terminals have been found adjacent to adrenal parenchyma and blood vessels in rat and human adrenal cortices. Although the function of preganglionic innervation of the cortex is not entirely clear, there are experimental reports documenting that in the rat the splanchnic nerve plays a role in regulating the prefeeding increase in corticosterone secretion. Although vagal sensory innervation of the adrenal is present, parasympathetic motor innervation of the adrenal is not as clearly defined.

Interactions between Stress and Androgens

Summary

Glossary

<i>Concentration gradient</i>	A region consisting of a high concentration of a compound adjacent to an area of low concentration of that same compound.
<i>Coregulatory protein</i>	A protein that interacts with a transcription factor and the transcriptional machinery. Coregulatory proteins have a profound effect on transcription rate, either increasing (coactivator) or decreasing (corepressor) it.
<i>Diurnal rhythm</i>	A biological rhythm based on the 24-h day.
<i>Glucocorticoid</i>	A form of steroid hormone that is produced primarily by the adrenal glands and is released following stress.
<i>Lipophilic</i>	Affinity for fatty substances.
<i>Luteinizing hormone (LH)</i>	A peptide hormone that is released from the pituitary gland and promotes testosterone synthesis from within the testes.
<i>Promoter</i>	The regulatory region of a gene. Often promoters are upstream of the protein-encoding regions of a gene.
<i>RNA polymerase holoenzyme</i>	The complex of proteins that are directly involved in transcribing a gene.
<i>Steroid hormones</i>	A class of hormones that are derived from cholesterol.
<i>Transcriptional</i>	Pertaining to the process of synthesizing mRNA from a DNA template.
<i>Transcription initiation site</i>	The region of a gene to which the mRNA polymerase holoenzyme binds to begin transcription.

Androgens

Major Forms of Androgens

The term androgen is derived from the Greek roots *andro* (man) and *gennan* (to produce). The biological definition of an androgen is any substance that specifically promotes the growth of the male gonads. There are four major forms of circulating androgens. Testosterone (T) is the predominant form in males and is analogous to estrogen in females. Other common forms of androgens are dihydrotestosterone (DHT), androstenedione, dehydroepiandrosterone (DHEA), and its sulfonlated derivative, DHEAS. The most potent androgens are T and DHT, while DHEA/S and androstenedione are weak androgens. Both males and females produce all forms of androgens, though in differing amounts. The majority of androgens produced by males is T, which circulates at 10-fold higher levels than DHT. In females, the predominant forms of circulating androgens are DHEA/S followed by androstenedione and finally T. Overall, androgen levels are roughly 10-fold higher in males than in females. Androgen levels do, however, undergo a moderate daily variation in what is called a diurnal rhythm. In men, highest levels of testosterone are found in the bloodstream during the early morning hours, whereas low levels are found in the blood during the evening. In rodents, a nocturnal species, testosterone levels peak in the first few hours after nightfall. In women, cyclic variations in testosterone have been reported, with peak levels occurring during the preovulatory phase of the menstrual cycle.

Origins

In males, testosterone is produced largely by Leydig cells in the testes. In females, T is produced by the interstitial and stromal thecal cells in the ovaries. In addition to the gonadally derived testosterone that circulates at high levels in males, a small proportion is synthesized in target tissues from the testosterone precursors androstenedione and DHEA/S. These often circulate at relatively high levels in males but act only very weakly on their own. Dihydrotestosterone is synthesized to a limited extent in the gonads; the majority is locally converted from T in many androgen target tissues. Androstenedione and DHEA/S are largely produced by the adrenal cortex. Recent studies

have also demonstrated that the brain has the appropriate enzymes to produce androgens *de novo*. The extent to which this synthesis affects physiology remains to be determined. Androgen synthesis and metabolism can occur anywhere the enzymes that catalyze such reactions are present. Though the primary tissues of origin are presented above, precursors and metabolites are produced in many tissues.

Synthesis Pathways

The biosynthetic pathway that produces endogenous androgens is common to many steroid hormones and begins with the conversion of cholesterol to pregnenolone in the mitochondria of steroid-synthesizing cells. Cholesterol is composed of 27 carbon atoms, including a 17-carbon sterol backbone with an 8-carbon side chain. The major androgens including testosterone have no side chain and are composed of only 19 carbon atoms.

The enzymes that catalyze the steroid synthesis pathway belong to a family of iron-coordinating proteins called cytochrome P450 enzymes. The steps in the testosterone synthesis pathway are briefly described here and are detailed in [Figure 1](#). Regulation of testosterone synthesis begins at the level of cholesterol transport from cellular storage sites to the inner mitochondrial membrane by the steroidogenic acute regulatory protein. Once in the mitochondrion, the P450 side chain cleavage enzyme (P450_{scc} or CYP11A) catalyzes the oxidation and removal of the six carbon atoms that comprise the majority of the side chain on cholesterol. The product, pregnenolone, then diffuses passively out of mitochondria to the smooth endoplasmic reticulum. Here the actions of the P450_{c17} (CYP17) enzyme further shorten the side chain, removing all carbons, leaving only a ketone at the C17 position. The final two steps in testosterone biosynthesis are catalyzed by dehydrogenases, which

Figure 1 Schematic diagram depicting the biosynthetic pathway of androgens from cholesterol. Enzymes responsible for catalysis are designated in italics. The names of steroid molecules are shown in bold.

have specificity for the C3- and C17-bound oxygens, respectively. The dehydrogenase that converts the C3 ketone to a hydroxyl group also isomerizes the C5 double bond to a C4 double bond.

Metabolites of Testosterone

In target tissues, testosterone can be converted by further enzyme catalysis. Aromatase can convert testosterone to estrogen by oxidoreduction of the C3 ketone and removal of the C10 methyl group, which allows aromatization of the A ring in the sterol backbone. This leads to a product that has very different effects than the parent compound. Testosterone can also be converted by the enzyme 5α -reductase to DHT, which is a more potent androgen than testosterone. The primary site of DHT formation is in peripheral target tissues such as the prostate, liver, and skin. The local metabolism of testosterone to DHT allows the androgenic signal to be amplified in a tissue-specific manner. Excessive production of DHT has been shown to be a factor in prostate abnormalities, such as benign prostatic hyperplasia (BPH). The pharmacological inhibition of 5α -reductase, such as with the compound finasteride, has proven to be an effective therapeutic agent.

DHT concentrations in androgen-dependent tissues are maintained through the direct formation of DHT from circulating testosterone and from the interconversion of DHT and 3α -diol, a primary metabolite of DHT. This bidirectional catalysis is accomplished by the actions of the oxidoreductase 3α -hydroxysteroid dehydrogenase (3α HSD) and, to a lesser extent, 3β HSD and 17β HSD10. A variety of enzymes also convert DHT to 3β -diol, including 3β HSD, 3α HSD, and 17β HSD7; however, this process is irreversible. While DHT is a pure androgen, binding and activating only androgen receptors (AR), the metabolite 3β -diol has very low affinity for the AR and preferentially binds the beta form of estrogen receptors. In the prostate, 3β -diol has been implicated in the regulation of epithelial cell proliferation. 3β -diol is ultimately converted to the inactive compounds 6α - or 7α -triol and excreted in the urine.

Secretion and Transport

Steroid hormones are lipophilic and thus can easily pass through cell membranes. For this reason, they are secreted along a concentration gradient from synthetic cells to the circulating plasma and do not need to be secreted by a vesicular membrane fusion pathway. Consequently, circulating levels of androgens accurately reflect rates of synthesis. There are, however, circulating plasma-binding proteins known as

the steroid hormone-binding globulins (SHBGs) that bind to testosterone and related compounds and transport them throughout the organism. Nonspecific interactions with other plasma proteins such as serum albumin also occur. The SHBGs can protect the steroids from degradative enzymes that shorten their half-life and can prevent renal excretion. Once at a target tissue, steroid hormones are able to easily enter cells by diffusing across the plasma membrane. Once in the cell, steroid hormones are bound by intracellular receptors. In the case of androgens such as T and DHT, the specific receptor has been termed the androgen receptor (AR).

The Androgen Receptor

Molecular Organization

Androgen receptors are dynamic proteins that are members of a superfamily of nuclear receptor proteins. This superfamily has a common structure composed of functional domains, depicted schematically in [Figure 2a](#). The domains include a hormone-binding domain near the C-terminus and a DNA-binding domain near the center of the linearized protein. The other domains include a hinge region to facilitate conformational change and a transactivation domain, which is important for interaction of the steroid receptor with transcriptional machinery. In the absence of hormone, the androgen receptor is maintained in an inactive state by a complex of chaperone proteins called heat shock proteins.

Function

Classically, the AR is a nuclear transcription factor and modulates gene expression in a hormone-dependent manner. In this respect, hormone binding induces a conformational change that dissociates the heat shock protein from the receptor, thus activating the receptor. The activation pathway of ARs by hormone is depicted in [Figure 2b](#). The conformational change sequesters the ligand-binding domain with hormone attached into a hydrophobic pocket and reveals the DNA-binding domain, which has high affinity for certain DNA sequences called hormone response elements (HREs). Upon activation, other regions are revealed that allow dimerization with other hormone-bound androgen receptors. The activated dimers then are able to bind to the HREs, a palindromic sequence of nucleotides in DNA. These HREs are not present in the promoter region of all genes, only those that are androgen responsive. Examples of such genes are the cytokine, interleukin-6, and the androgen receptor itself.

Figure 2 Schematic diagram of (a) androgen receptor (AR) functional domains and (b) pathway for activation of gene transcription. HRE, hormone response element; HSP, heat-shock protein. Cell membrane is depicted as a broad bar separating the cytoplasm from the extracellular space. Dashed line indicates nuclear membrane. DNA of androgen-responsive gene is shown as a rectangle in the nucleus.

Coregulatory Proteins

The control of gene expression by ARs is also dependent on factors such as the appropriate promoter context and the cell-specific presence of coregulatory proteins. Once the activated AR is bound to the HRE, for gene expression to occur it still must communicate on a molecular level with the RNA polymerase holo-enzyme, which occupies the transcription initiation site. It is generally accepted that this contact is not direct, but occurs through coregulatory proteins that do not bind to DNA directly but act through protein-protein contacts.

Nongenomic Androgen Actions

Hormone-dependent transcription is the primary mechanism of action for ARs; however, a growing body of evidence suggests that androgens can act rapidly, within seconds to minutes, to affect cell function, suggesting the presence of a nongenomic pathway. These nongenomic effects involve the activation of second

messenger signaling cascades that result in the phosphorylation of a variety of transcription factors. Historically, ARs were thought to be inactive prior to localization in the nucleus; however, the observed rapid effects of androgens have forced the reevaluation of this hypothesis. One possibility is that the AR, following ligand binding and dissociation of heat shock proteins, is able to associate with the plasma membrane through interactions with G-protein-coupled receptors. In addition, androgens can bind directly to the SHBG receptor, also localized in the plasma membrane, and activate the mitogen-activated kinase second messenger system. However, to date a true membrane androgen receptor has not been identified.

Physiological Actions of Androgens

The specific set of genes that is regulated by androgens leads to diverse physiological functions. In general, growth-associated processes are involved, such as those in prostate, hair, skin, muscle, and

bone. Typical examples of androgen-dependent functions are those associated with puberty in males. Increasing levels of T during the mid-teen years lead to a deepening of the voice, growth of facial and axillary hair, activation of sebaceous glands, coarsening of the skin, and growth of long bones and muscle. Androgens also regulate spermatogenesis, a process that is initiated as testicular size increases during puberty. Spermatogenesis persists throughout the life of the male but begins to decline as circulating testosterone levels decline.

Androgen-Associated Pathology

As noted previously, androgens are involved in many anabolic processes. When these growth processes go awry in the testes or prostate, cancerous pathology can result. One of the most common treatments for prostate cancer is to block androgen receptor function with antagonist drugs.

Some of the developmental defects associated with malfunctioning androgen signaling have led to the discovery of specific androgen functions. The most common syndrome associated with a nonfunctional androgen receptor is called androgen insensitivity syndrome or tfm (testicular feminized male). This rare disorder in genetic males results in a phenotypically female individual with breast development, a lack of pubic hair, and formation of feminized genitalia. Another syndrome showing hermaphroditism is a defect in the 5 α -reductase gene. Individuals with this defect cannot produce DHT and thus have ambiguous genitalia until puberty, when testosterone levels rise and partially compensate for the DHT deficiency.

Interactions between Stress and Androgens

Studies using animal models have shown that stress can affect circulating levels of testosterone, and testosterone can influence responses to stress. Observations of baboons in their natural habitat have shown that in response to a stressful stimulus, testosterone levels respond differently depending on the animal's rank in a dominance hierarchy. Dominant males show an increase in testosterone levels following stress, while subordinate males' testosterone levels

decrease. The reason for this differential response appears to be related to the animal's normal circulating level of glucocorticoids. The subordinate males are in a state of chronic stress based on an elevated basal level of circulating glucocorticoids. In contrast, dominant males have low basal levels of circulating glucocorticoids. In response to an acute stressor, both dominant and subordinate males show rapid increases in circulating glucocorticoid levels and decreases in luteinizing hormone secretion. However, dominant males appear to be less sensitive to the inhibitory effects of glucocorticoids on testosterone production. This differential response of testosterone levels to stressful stimuli promotes the reproductive fitness of the dominant males while reducing that of subordinate males.

Summary

The androgens are best known for their functions in reproduction and anabolic growth, though they have been shown to be important for other physiological functions such as regulating stress responses and neural development. Ongoing research is attempting to more precisely identify the role of androgens in cognitive functioning.

Anger Dyscontrol and Regulation

Anger Treatment

Glossary

<i>Aggression</i>	Behavior intended to cause psychological or physical harm to someone or to a surrogate target. The behavior may be verbal or physical, direct or indirect.
<i>Anger</i>	A negatively toned emotion, subjectively experienced as an aroused state of antagonism toward someone or something perceived to be the source of an aversive event.
<i>Anger reactivity</i>	Responding to aversive, threatening, or other stressful stimuli with anger reactions characterized by automaticity of engagement, high intensity, and short latency.
<i>Cathartic effect</i>	The lowering of the probability of aggression as a function of the direct expression of aggression toward an anger instigator. The lowering of arousal associated with such catharsis is more or less immediate and can be reversed by re-instigation.
<i>Escalation of provocation</i>	Incremental increases in the probability of anger and aggression, occurring as reciprocally heightened antagonism in an interpersonal exchange.
<i>Excitation transfer</i>	The carryover of undissipated arousal, originating from some prior source, to a new situation having a new source of arousal, which then heightens the probability of aggression toward that new and more proximate source.
<i>Hostility</i>	An attitudinal disposition of antagonism toward another person or social system. It represents a predisposition to respond with aggression under conditions of perceived threat.
<i>Inhibition</i>	A restraining influence on anger expression. The restraint may be associated with either external or internal factors.

Anger and Stress

Anger is a negatively toned emotion, subjectively experienced as an aroused state of antagonism toward someone or something perceived to be the source of an aversive event. It is triggered or provoked situationally by events that are perceived to constitute deliberate harm-doing by an instigator toward oneself or toward those to whom one is endeared. Provocations usually take the form of insults, unfair treatments, or intended thwartings. Anger is prototypically experienced as a justified response to some wrong that has been done. While anger is situationally triggered by acute, proximal occurrences, it is shaped and facilitated contextually by conditions affecting the cognitive, arousal, and behavioral systems that comprise anger reactions. Anger activation is centrally linked to threat perceptions and survival responding.

As a normal human emotion, anger has considerable adaptive value, although there are sociocultural variations in the acceptability of its expression and the form that such expression takes. In the face of adversity, it can mobilize psychological resources, energize behaviors for corrective action, and facilitate perseverance. Anger serves as a guardian to self-esteem, operates as a means of communicating negative sentiment, potentiates the ability to redress grievances, and boosts determination to overcome obstacles to our happiness and aspirations. Akin to aggressive behavior, anger has functional value for survival.

Despite having multiple adaptive functions, anger also has maladaptive effects on personal and social well-being. Generally, strong physiological arousal impairs the processing of information and lessens cognitive control of behavior. Because heightened physiological arousal is a core component of anger, people are not cognitively proficient when they become angry. Also, because the activation of anger is accompanied by aggressive impulses, anger can motivate harm toward other people, which in turn can produce undesirable consequences for the angered person, from direct retaliation, loss of supportive relationships, or social censure. An angry person is not optimally alert, thoughtful, empathic, prudent, or physically healthy. Being a turbulent emotion ubiquitous in everyday life, anger is now known to be substantially associated with stress-related cardiovascular disorders, both coronary heart disease and essential hypertension. Anger is also a symptom of posttraumatic stress disorder (PTSD), and it has high relevance to the PTSD derivative of violent crime

victimization and especially to combat or war zone exposure.

The Experience and Expression of Anger

There is a duality of psychosocial images associated with anger experience and anger expression. The emotional state is depicted as eruptive, destructive, unbridled, savage, venomous, burning, and consuming but also as energizing, empowering, justifying, signifying, rectifying, and relieving. The metaphors, on the one hand, connote something pressing for expression and utilization, but on the other, imply something requiring containment and control. This duality in psychosocial imagery reflects conflicting intuitions about anger, its expression, and its consequences that abound in ordinary language and are reflected in both scholarly literature and artistic works from the classical period to contemporary times. This Janus-faced character of anger foils attempts to understand it and to therapeutically intervene with recurrently angry individuals.

The facial and skeletal musculature are strongly affected by anger, mobilized by a mixture of adrenaline and noradrenaline hormonal secretions. The face becomes flushed, and the brow muscles move inward and downward, fixing a hard stare on the target. The nostrils flare, and the jaw tends toward clenching. This is an innate pattern of facial expression that can be observed in toddlers. Tension in the skeletal musculature, including raising of the arms and adopting a squared-off stance, are preparatory actions for attack and defense. The muscle tension provides a sense of strength and self-assurance. An impulse to strike out accompanies this subjective feeling of potency. From an evolutionary perspective, our perceptual system has been shaped to detect angry faces rapidly, especially those of angry males.

When people report anger experiences, they most typically give accounts of things that have happened to them. For the most part, they describe events physically and temporally proximate to their anger arousal. As a rule, they provide accounts of provocations ascribed to events in the immediate situation of the anger experience. This fosters the illusion that anger has a discrete external cause. The provocation sources are ordinarily identified as the aversive and deliberate behavior of others; thus, anger is portrayed in the telling as being something about which anger is quite fitting. People are very much inclined to attribute the causes of their anger to the personal, stable, and controllable aspects of another person's behavior.

However, the response to the question "What has made you angry?" hinges on self-observational

proficiencies and is often based on intuitions. Precisely because getting angry involves a loss in self-monitoring capacity, people are neither good nor objective observers when they are angry. When inspecting any particular episode, the immediate causes of the anger are readily identifiable. Far less commonly do people disaggregate their anger experiences into multi-causal origins, some of which may be prior, remote events and ambient circumstances, rather than acute, proximal events. Anger experiences are embedded or nested within an environmental-temporal context. Disturbances that may not have involved anger at the outset leave residues that are not readily recognized but that operate as a lingering backdrop for focal provocations.

Anger is inherently a disposition to respond aggressively, but aggression is not an automatic consequence of anger because aggressive behavior is regulated by inhibitory control mechanisms, engaged by internal and external cues. In this regard, physical constraints, expectations of punishment or retaliation, empathy, consideration of consequences, and prosocial values operate as regulatory controls on aggression. While the experience of anger creates a readiness to respond with aggression, that disposition may be otherwise directed, suppressed, or reconstituted. Thus, the expression of anger is differentiated from its experience.

One aspect of anger that influences the probability of aggression is its degree of intensity. The higher the level of arousal, the stronger the motivation for aggression and the greater the likelihood that inhibitory controls will be overridden. Strong arousal not only impels action, but also impairs cognitive processing of aggression-mitigating information. A person in a state of high anger arousal is perceptually biased toward the confirmation of threat, is less able to attend to threat-discounting elements of the situation, and is not so capable of re-appraising provocation cues as benign. Because anger and aggression occur in a dynamic interactional context, the occurrence of aggression will, in turn, influence the level of anger. Thus, anger reactivity can be seen as a mode of responding characterized by automaticity, high intensity, and short latency.

Important forms of the dynamic interrelation of anger and aggression are the escalation of provocation and the cathartic effect. Escalation involves increases away from equilibrium, whereby succeeding events intensify their own precursors. In the case of anger and aggression, escalation refers to incremental change in their respective probabilities, occurring as reciprocally heightened antagonism in an interpersonal exchange. Anger-elicited aggression may evoke further anger in response, progressively generating justification for retaliation. In contrast,

when physical aggression is deployed by an angry person against the anger instigator and there is no retaliation, anger arousal and further aggression are diminished. This is called the cathartic effect – its conditions should not be confused (as they often are) with those involving aggression by non-angry people, vicarious or observed aggression, or aggression not received by the anger instigator. However, the arousal-reducing effect of aggression carried out by angry people against those who have made them angry is reinforcing of aggressive behavior. This means that when anger is reinstated by a new provocation, the likelihood of aggressive behavior is increased. The cathartic expression of anger, whether through destructive aggression or through verbal communication intended to be constructive, can be understood as an organismic action to restore equilibrium.

An alternative to the deliberate expression of anger is suppression, which is largely a product of inhibitory controls. Anger suppression can be functional in promoting interpersonal or social conciliation. For example, when there is a high probability of impending violence, it is prudent to restrain anger expression to diminish the likelihood of triggering a physical assault. Whether in a domestic, occupational, or street context, anger is adaptively muffled when physical retaliation can be expected or when a cool head is needed to solve a problem. In the short term, suppressing even the verbalization of anger not only may be beneficial interpersonally, but also may lead to more regulated physiological reactivity levels. However, recurrent deployment of anger suppression as a stress-coping style will most likely have deleterious effects on cardiovascular health, as has been found for essential hypertension.

Because anger and aggression are thought to be differentially socialized for males and females, the question of gender differences in the experience and expression of anger arises. It has generally been found that the anger of women is comparable to that of men from the standpoint of experienced intensity. However, the style of anger expression varies by gender, especially according to the context of anger activation and its anticipated consequences. Males are more likely to be angered in a public place or by impersonal triggers, whereas females are more likely to be angered at home or by being let down by someone close to them. Females are more likely to become angered by verbal aggression and insensitive/condescending behavior, and males are more likely to be angered by behavior causing physical harm. Men, when angered, are more inclined to use physical aggression than women, who in turn are more likely to fear aggressive retaliation.

Anger Physiology

A defining condition of anger is physiological arousal, the activation of which has evolutionary roots. For our prehistoric ancestors, when a threat to survival or survival resources was detected, it was advantageous to be mobilized to respond energetically and to sustain effort. The flight-or-fight response refers to this hard-wired physiological mechanism that gets instantaneously triggered to engage survival behavior, to focus attention on the survival threat, and to enable the organism to not succumb to pain. Anger is the emotional complement of the organismic preparation for attack, which also entails the orchestration of signals of attack readiness so as to ward off opponents or to coerce compliance.

The arousal of anger is marked by physiological activation in the cardiovascular, endocrine, and limbic systems, as well as other autonomic and central nervous system areas, and by tension in the skeletal musculature. The autonomic signature of anger corresponds to a mixture of adrenaline and noradrenaline. Autonomic system arousal, especially cardiovascular, has been commonly observed in conjunction with anger by scholars from the classical age (such as Seneca, Aristotle, and Plutarch) to the early behavioral scientists of the nineteenth and twentieth centuries (especially Charles Darwin, William James, G. Stanley Hall, and Walter B. Cannon). Laboratory research has reliably found anger arousal to entail increases in both systolic and diastolic blood pressure and, to a somewhat lesser extent, heart rate. It is differentiated from fear by a stronger increase in diastolic pressure, in muscle electrical activity (measured by electromyogram recordings), and in total peripheral resistance. Associated with this cardiovascular activation is facial flushing, which is often reported by people reflecting on their anger experience and also is measured by face temperature. Indeed, in terms of psychosocial imagery, there is no better metaphor for anger than hot fluid in a container.

Autonomic arousal is primarily engaged through adrenomedullary and adrenocortical hormonal activity. The secretion by the adrenal medulla of the catecholamines adrenaline and noradrenaline and by the adrenal cortex of glucocorticoids provides a sympathetic system effect that mobilizes the body for immediate action (e.g., the release of glucose, stored in the liver and muscles as glycogen). In anger, the catecholamine activation is more strongly noradrenaline than adrenaline (the reverse being the case for fear). The adrenocortical effects, which have longer duration than the adrenomedullary ones, are

mediated by secretions of the pituitary gland, which also influences testosterone levels. The pituitary-adrenocortical and pituitary-gonadal systems are thought to affect readiness or potentiation for anger responding.

The central nervous system structure that has been identified in anger activation is the amygdala, the almond-shaped limbic system component located deep in the temporal lobe. The amygdala is the key site for aversive motivational system. Activation in the corticomedial amygdala is associated with anger and attack priming. Anger has also been linked with left-prefrontal cortical activity, which has typically been associated with positive affect and approach motivation. The central nervous system neurotransmitter serotonin, which is also present in blood platelets, affects anger potentiation, as low levels of this hormone are associated with irritable mood. Serotonin imbalances are related to deficits in the modulation of emotion. While serotonin and other neurotransmitters (noradrenaline and dopamine) are involved in anger activation, the neural structures and circuitry in anger dysregulation remain to be disentangled.

These various physiological mechanisms thus pertain not only to the intensity of anger arousal but also to its duration. Arousal activation eventually decays to baseline levels, but recovery time may be prolonged by exposure to new arousal sources or by rumination. The potency of a provocation may be heightened by the carryover of undissipated excitation from a prior arousal source, which may not have been anger specific (i.e., an otherwise stressful circumstance, such as exposure to bad news, work pressure, or traffic congestion). This excitation transfer of arousal residues facilitates anger, augments its intensity, amplifies blood pressure, and raises the probability of aggression. Residual arousal from unresolved anger events can transfer to future conflicts and further intensify anger reactivity to instigating events. In turn, unexpressed anger is associated with exaggerated and more prolonged cardiovascular responses to a variety of stressful stimuli.

In this regard, a stress framework is highly useful. It is unquestionably the case that physiological arousal is activated by exposure to commonly identified stressors, such as noise, crowding, difficult tasks, and high-pressure job environments filled with time demands or exposure to abrasive interactions. Both acute and prolonged exposure to such conditions may induce physiological activation that decays slowly. Therefore, when someone experiences an event that pulls for the cognitive label anger and this event occurs concurrently with already elevated arousal, the anger system is then more easily engaged.

Cognition, Anger, and Threat

Humans have elaborate neurocognitive systems for detecting threat. We have a neural architecture (especially the limbic system) specialized for the processing of emotion and emotion-cognition interactions, and the amygdala is centrally involved in detecting events as threats. In parallel, higher level cognitive reasoning elaborates this information, in what are termed appraisal processes. The perception of threat is conjoined with sympathetic nervous system activation of autonomic arousal components, such as heart rate, blood pressure, and respiration increases, that prepare the body for emergency action.

In addition to potentiating action, anger in such states of mobilization has adaptive value as a source of information. To others, it communicates perceived wrongdoing, threat of aggression, or intent of reprisal. Such information exchange prior to aggression can facilitate social and interpersonal negotiations toward conflict resolution. For the self, it serves as information for prioritizing and decision making. The intensity of anger, for example, can help focus and maintain attention on relevant goals and help one estimate progress toward those goals. When pressed to make a decision, anger serves as a summary affective cue that can be processed without need for elaborate analysis.

To get angry about something, one must pay attention to it. Anger is often the result of selective attention to cues having high provocation value. A principal function of cognitive systems is to guide behavior, and attention itself is guided by integrated cognitive structures, known as schemas, that incorporate rules about environment-behavior relationships. What receives attention is a product of the cognitive network that assigns meaning to events and the complex stimuli that configure them. Expectations guide attentional search for cues relevant to particular needs or goals. Once a repertoire of anger schemas has been developed, events (e.g., being asked a question by someone) and their characteristics (e.g., the way the question was asked, when it was asked, or who asked it) are encoded or interpreted as having meaning in accord with the pre-existing schema. Because of their survival function, the threat-sensing aspect of anger schemas carries urgent priority and can pre-empt other information processing.

Since the writings of the Stoic philosophers of the classical period, anger has been understood to be strongly determined by personal interpretations of events. The concept of appraisal is that of interpretation, judgment, or meaning embedded in the perception of something – not as a cognitive

event occurring after that something has happened. The appraisal of provocation is in the seeing or hearing. Appraisal, though, is an ongoing process, so various reappraisals of experience will occur and will correspondingly affect whether or not the probability of aggression is lessened, maintained, or intensified. Rumination about provoking circumstances will of course extend or re-vivify anger reactions. In addition, the occurrence of certain thoughts can prime semantically related ideas that are part of an anger schema.

Perceived malevolence is one of the most common forms of anger-inducing appraisal. When another person's behavior is interpreted as intending to be harmful to oneself, anger and aggression schemas are activated. In turn, receiving information about mitigating circumstances (e.g., learning that the person was fatigued and working overtime) can defuse the appraisal of personal attack and promote a benign reappraisal. Perceiving malevolence pulls for anger by involving the important theme of justification, which includes the externalization of blame. When harm or injustice has been done, the social norms of retaliation and retribution are engaged. Indeed, one view of anger is that it is a socially constituted syndrome or a transitory social role governed by social rules. Thus, its meaning and function would be determined by the social systems in which it occurs and of which it is an integral part.

Justification is a core theme with regard to the activation of anger and aggression, being rooted in ancient religious texts, such as the Bible and the Koran, as well as classical mythologies about deities and historical accounts of the behavior of ancient rulers. Correspondingly, anger and physical aggression are often viewed as ways of applying a legitimate punitive response for transgression or as ways of correcting injustice. Frequently, however, an embellished justification serves the exoneration of blame for destructive outcomes of expressed anger.

As people monitor their physical and social environment for threats to their resources or self-esteem, they operate with expectations about how events and the behavior of others will unfold. When opposition, anger, or antagonism is expected, this can lead to selective perception of situational cues in line with an aggressive script, a cognitive programming that guides behavior. Anger arousal provides energy and justification for aggressive script enactment.

Anger Dyscontrol and Regulation

Anger is a highly functional human emotion, and it is one to be appreciated as a rich part of cultural life, but the survival value of the aggression-enabling function of anger is an archaic remnant with rare

contemporary necessity. The challenges presented by civilized society are predominantly psychological, rather than physical, thus attenuating anger's adaptive worth. Effective coping with the demands of modern life requires understanding complex information, problem solving, and prudent action, not energized rapid responding. Even in emergency situations, anger requires regulation. Contrary to intuitions, anger can be detrimental to survival in a physical threat crisis. It is counterproductive for energy conservation in a prolonged fight, for monitoring additional threat elements and hazards, and for effective strategy selection in circumstances in which survival threat lingers and/or remains obscure. The regulation of the intensity and duration of anger arousal is pivotal to its merit or utility.

While the physiological components of anger, such as increased blood flow, may be adaptive for survival in a short-term danger episode, the by-products of recurrent engagement of anger are hazardous in the long term. Unregulated anger commonly has been found to be associated with physical and psychological health impairments. In the realm of physical health, chronic anger has been established as having detrimental effects most centrally on the cardiovascular system, and these are related to mortality. Persons high in generalized hostility who are reactively angry are at considerable risk for coronary heart disease. When such persons are confronted with a stressful demand, they have strong cardiovascular responses in blood pressure, neurohormonal secretions, and cholesterol. A hostile, cynical, and distrusting outlook also necessitates high vigilance for thwarting and malevolence, resulting in prolonged neurohormonal activation conducive to atherosclerosis.

In addition to these pathogenic effects for a personality style that is overly expressive of anger, the coronary system is also impaired by recurrently suppressed anger and has long been identified as a causal variable in the etiology of essential hypertension. People who have difficulties expressing anger tend to be at risk for chronically elevated blood pressure, as mediated by high plasma renin activity and nor-adrenaline. The suppression of anger has been robustly correlated to elevated blood pressure in laboratory studies and to sustained hypertension in field studies. Also, studies using ambulatory recorders of blood pressure have found that persons who are high in hostility and who have a tendency to inhibit the expression of that hostility have greater cardiovascular reactivity to provocation events, as well as elevated resting blood pressure.

With regard to psychological well-being, anger occurs in conjunction with a wide range of

psychiatrically classified disorders, including a variety of impulse control dysfunctions, mood disorders, personality disorders, and forms of schizophrenia, especially paranoid schizophrenia. In addition, the activation of anger has long been recognized as a feature of clinical disorders that result from trauma, such as dissociative disorders, brain damage syndromes, and, especially, PTSD. Anger also appears in mental state disturbances produced by general medical conditions, such as dementia, substance abuse disorders, and neurological dysfunctions resulting from perinatal difficulties.

Among hospitalized psychiatric patients in long-term care in both civil commitment and forensic institutions, anger is a salient problem, as identified by both clinical staff and the patients themselves. Importantly, it is linked to assaultive behavior by psychiatric patients both inside and outside such facilities. Such patients typically have traumatic life histories, replete with experiences of abandonment and rejection, as well as economic and psychological impoverishment. For them, anger becomes entrenched as a mode of reactance to stressful or aversive experiences, and it is a significant aspect of their resistance to treatment. Chronically angry people are reluctant to surrender the anger-aggression system that they have found useful to engage and because they discount the costs of its engagement. Psychiatric hospital staff, especially those on acute admissions units and in long-term institutions, have very stressful occupations as a result of the anger episodes of the patients in their care. Posttraumatic stress disorder commonly occurs among staff who have been victims of assault by patients.

Anger Treatment

In the treatment of anger disorders, cognitive-behavioral therapy (CBT) approaches have been found to be effective with a wide range of clinical populations. CBT approaches incorporate many elements of behavior therapy, such as training in self-monitoring, relaxation, and social skills, but also centrally seek to modify cognitive structures and the way in which a person processes information about social situations. They strongly emphasize self-regulation, cognitive flexibility in appraising situations, arousal control, and learning prosocial values and scripts. By making extensive use of therapist modeling and client rehearsal, anger proneness is modified by first motivating client engagement and then restructuring cognitive schemas, increasing capacity to regulate arousal and facilitating the use of constructive coping behaviors.

A misleading aspect of the notion of anger management is that it implies that treatment is centrally

about what to do when one gets angry. Instead, a very significant objective of anger treatment is about how to not get angry in the first place – hence the priority given to regulatory controls for anger experience or activation. The parameters or state markers for anger activation that receive attention in CBT anger treatment are reactivity (frequency on onset and how easily anger is triggered), latency (how rapidly activated), intensity (how strongly engaged), and duration (persistence of arousal). Treatment aims to minimize anger reactivity, intensity, and duration and to moderate anger expression to reduce the costs of anger dyscontrol.

To facilitate anger regulation, anger treatment procedures strive to disconnect anger from the threat system. This is done first through the provision of safety, patience, and psychological space for reflection, exploration, and choice. The client's view of anger is normalized, to obviate worries about being a bad or unworthy person. The therapist acknowledges the legitimacy of the client's feelings, affirming his or her self-worth. Building trust in the therapeutic relationship is pivotal. As self-regulation hinges on knowledge, education about anger and discovery of the client's personal anger patterns or anger signature is facilitated. Much is done to augment self-monitoring and to encourage the moderation of anger intensity. As tension or strain may surface in the course of treatment, the therapist models and reinforces non-anger alternative responding so as to build replacements for the automatized angry reactions that had been the client's default coping style.

One CBT approach to anger treatment that has received significant support for its efficacy is called stress inoculation (SI). In this treatment approach, anger provocation is simulated by therapeutically paced exposure to anger incidents created in imaginal visualization and in role play. The progressively graduated exposure, directed by the therapist, involves a hierarchy of anger incidents produced by the collaborative work of client and therapist. This graduated, hierarchical exposure, done in conjunction with the teaching of stress coping skills, is the basis for the inoculation metaphor.

The SI approach to anger treatment involves the following key components: (1) client education about anger, stress, and aggression; (2) self-monitoring of anger frequency, intensity, and situational triggers; (3) construction of a personal anger provocation hierarchy, created from the self-monitoring data and used for the practice and testing of anger coping skills; (4) arousal reduction techniques of progressive muscle relaxation, breathing-focused relaxation, and guided imagery training; (5) cognitive restructuring by altering attentional focus, modifying appraisals,

and using self-instruction; (6) training behavioral coping in communication and respectful assertiveness as modeled and rehearsed with the therapist; and (7) practicing the cognitive, arousal regulatory, and behavioral coping skills while visualizing and role playing progressively more intense anger-arousing scenes from the personal hierarchies.

Components of the Renin–Angiotensin System
Endocrine Plasma Renin–Angiotensin System
Paracrine Tissue Renin–Angiotensin System
Renin–Angiotensin System and Stress

Glossary

Blood–brain barrier

A term for the impermeability of the endothelial cells of cerebral capillaries to components of the blood, due *inter alia* to tight junctions, so that endo- and transcytotic transport across the capillary wall occurs in a highly specific and regulated manner.

Cardiovascular control

Control of cardiovascular homeostasis by neural and local mechanisms.

Cardiovascular homeostasis

The maintenance of the cardiovascular parameters, especially blood pressure and blood volume at levels optimal for blood supply to all organs.

Components of the Renin–Angiotensin System

Angiotensinogen

Angiotensinogen (AOPEN) is the only known precursor molecule to be converted by the renin–angiotensin system (RAS) into active angiotensins. It is a glycoprotein with a molecular weight between 61 and 65 kDa, and it shows close structural similarities to the serine protease inhibitor family. Originally found to be synthesized in the liver, AOPEN is known to be present in several other organs, especially in glial cells of the brain.

Renin

Renin is a very specific aspartyl proteinase whose only known substrate is AOPEN. Renin cleaves the decapeptide angiotensin I (Ang I) from the N-terminus of mature AOPEN. Renin is produced primarily by

the kidney and released into the circulation, but is also produced in other tissues. Renin synthesis is stimulated by the sympathetic nervous system and by loss of volume and sodium.

Angiotensin Converting Enzyme

Angiotensin converting enzyme (ACE) is a dipeptidyl-carboxypeptidase that cleaves the C-terminal histidine-leucine of Ang I to generate angiotensin II (Ang II). It is found in high concentrations in the lung, kidney, and heart and is distributed throughout the brain. High amounts are detected in areas lacking the blood–brain barrier such as the diencephalon, pituitary, and pineal gland. ACE is also able to hydrolyze other substrates, such as bradykinin, opioid peptides, and substance P. Thus, ACE is additionally involved in physiological mechanisms beyond the RAS.

Active Angiotensins

The best studied peptide of the system is Ang II, and the functions of the RAS are largely attributed to this active metabolite. Besides Ang II, additional peptides of the RAS have been found to be biologically active, such as Ang III, Ang IV, and Ang II(1–7). In fact, Ang III may be even more potent than Ang II in the brain when acting on a common receptor. Ang II(1–7) can be formed via an ACE-independent mechanism and has the same potency as Ang II in vasopressin release. Studies on Ang IV suggest a biological role for this peptide as well.

There is evidence that proteases other than renin and ACE can produce bioactive angiotensin species. Such proteases include ACE 2, cathepsin G, tonin, tissue plasminogen activator, chymase, and other neutral peptidases.

Receptors

The use of highly specific ligands has led to the description and cloning of two main Ang II receptors, namely AT₁ and AT₂. Most of the known classical cardiovascular effects of Ang II are attributed to the AT₁ receptor. In contrast to humans, two different subtypes have been found for this receptor in rodents: AT_{1a} and AT_{1b}. Whereas AT_{1a} has been localized in blood vessels, kidney, lung, liver, and specific brain areas that are involved in the control of blood pressure and fluid homeostasis, AT_{1b} receptors were originally described in glandular tissues, such as the anterior pituitary and adrenal gland.

Endocrine Plasma Renin-Angiotensin System

The endocrine RAS is dependent on renin released by the kidney into the blood, so that AOPEN is cleaved

in the circulation to liberate the inactive decapeptide Ang I. ACE then cleaves Ang I to yield the octapeptide Ang II, the active molecule of the system. Circulating Ang II is one of the most potent vasoconstrictors and acts on specific receptors to elicit the following localized effects:

- constriction of the vasculature
- reabsorption of sodium and water in the kidney
- release of aldosterone from the adrenal glands
- induction of inotropic and arrhythmogenic effects in the heart
- incitement of thirst at specific brain areas outside the blood–brain barrier

Figure 1 summarizes the roles of the RAS in cardiovascular and fluid–electrolyte regulation.

Paracrine Tissue Renin-Angiotensin System

In addition to the circulating RAS, a local formation and action of Ang II has been observed at the level of various organs. The components of the RAS have been detected in several tissues including the heart, vasculature, kidney, adrenal glands, and brain. The local formation and action of Ang II in peripheral organs can therefore occur independent from the circulating RAS. However, RAS components required for angiotensin synthesis, such as renin and AOPEN, can be also taken up from the circulating blood. The latter is possible only for organs accessible to blood proteins, such as the kidney, heart, adrenal glands, and brain areas situated outside the blood–brain barrier. Nevertheless, there are areas in the brain that are inaccessible to the circulating Ang II because of the blood–brain barrier but that express functional angiotensin receptors. In these brain regions, only locally formed angiotensins can act.

The tissue RASs seem to regulate long-term organ function and may be responsible for pathological structural changes. **Figure 2** illustrates the functions of the endocrine and tissue RASs.

Renin-Angiotensin System and Stress

Both physical and emotional stressors induce peripheral and central responses designed to preserve cardiovascular homeostasis. As one of the main regulators of cardiovascular homeostasis, the RAS is stimulated by stressors that lead to a lowering in the blood pressure, such as hemorrhage, loss of blood volume and sodium, or increased activity of the sympathetic nervous system. The RAS acts synergistically with the sympathetic nervous system, increasing blood pressure and maintaining organ perfusion, and electrolyte

Figure 1 Roles of the renin–angiotensin system in cardiovascular and fluid–electrolyte regulation.

Figure 2 Functions of the endocrine and tissue renin–angiotensin systems.

and volume balance. Recently, it has been demonstrated that Ang II is also an important mediator of inflammation by stimulating oxidative stress.

The physical and behavioral responses to stress are integrated at the level of the central nervous system, including areas known to regulate the homeostasis of the *milieu interieur*. AOGEN and the angiotensin receptors are present in areas responsible for the maintenance of homeostasis, such as the hypothalamic and brain-stem nuclei (Figure 3), and participate in the stress response.

The sympathetic nervous system, the component of the autonomic nervous system that is essentially involved in the fight-or-flight reaction, is modulated by the RAS not only in the periphery but also in central areas of autonomic control. During the reaction to stress, there is an increase in blood levels of renin in addition to epinephrine. In the central nervous system, an interrelationship between the activity of the brain RAS and the sympathetic system and other central autonomic pathways has also been shown. Stress-induced brain RAS activation may

Figure 3 Angiotensin sites involved in the central control of homeostasis.

Figure 4 Stress-induced brain RAS activation may induce renin release from the kidney, possibly through sympathetic pathways.

induce renin release from the kidney, possibly through sympathetic pathways (Figure 4).

Various stressor agents activate the hypothalamic-pituitary axis. Ang II, together with other neurotransmitters and neuromodulators, modulates the activity of the hypothalamic-pituitary axis and stimulates the release of vasopressin and corticotropin-releasing factor (CRF). In addition, it has been proposed that the brain RAS is involved in behavioral responses, such as cognition, memory, and central analgesia.

Prolonged overactivation of the RAS may lead to a disease state. Drugs that block the actions of the RAS, such as ACE or renin inhibitors and AT1 antagonists, are widely used for the treatment of various cardiovascular diseases, and their effectiveness may be

partially due to the inhibition of the brain RAS and thereby the attenuation of the sympathetic output and the stress response.

Angiotensin Receptors

Actions of Angiotensin

Pathophysiology of the RAS

The RAS and Stress

Glossary

<i>Angiotensin-converting enzyme (ACE)</i>	Enzyme that converts angiotensin I to angiotensin II.
<i>Angiotensin II receptors</i>	The two classes of Ang II receptors, AT ₁ and AT ₂ , occur in a variety of tissues, including brain, adrenal, heart, vessel wall, and kidney.
<i>Angiotensin II (Ang II)</i>	Octapeptide; a major active mediator of the renin-angiotensin cascade.
<i>Cardiovascular disease</i>	Disease of the heart and blood vessels.
<i>Hypertension</i>	High arterial blood pressure.
<i>Renin-angiotensin system (RAS)</i>	Hormone system that plays an important role in regulating body fluid balance, blood volume, arterial pressure, and cardiac, vascular, and renal function.

The physiological roles of the renin-angiotensin system (RAS) include regulation of blood pressure, fluid and electrolyte homeostasis, and aldosterone and pituitary hormone release. The octapeptide angiotensin II (Ang II) is the major active component of the RAS and is generated by cleavage of the substrate, angiotensinogen, through the successive actions of two proteolytic enzymes, renin and angiotensin-converting enzyme (ACE). Ang II acts via two receptors, AT₁ and AT₂. Although originally viewed solely

as a circulating system, all components of the RAS have been found in a variety of tissues, including brain, adrenal, heart, vessel wall, and kidney, suggesting the presence of tissue-specific systems participating in physiological and pathophysiological effects of the RAS (Figure 1).

Recently, the classical view of the RAS was changed by the discovery of the enzyme ACE2, a human homolog of ACE, and awareness that other angiotensin peptides, such as Ang IV and Ang 1–7, may have physiological actions.

Angiotensin Receptors

AT₁ Receptor

The AT₁ receptor mediates most of the classical actions of Ang II. It displays a seven transmembrane domain topology and is a member of the G-protein-coupled receptor family, with signaling predominantly via G_{q/11}, phosphoinositides, and calcium. In addition, AT₁ activation is linked to vascular and cardiac hypertrophy through transactivation of the epidermal growth factor (EGFR) and its signaling pathways, primarily through mitogen-activated protein (MAP) kinase activation. In rodents, two subtypes exist, AT_{1A} and AT_{1B}, which have 95% homology.

Many of the functions of Ang II are paralleled by the distribution of AT₁ receptors in cardiovascular, nervous, renal, endocrine, and reproductive tissues. In the central nervous system, AT₁ receptors are found in the circumventricular organs, including the subfornical organ (SFO) and vascular organ of the lamina terminalis (OVLT), and regions of the hypothalamus such as the paraventricular nucleus and median eminence, which regulate body fluid homeostasis. AT₁ receptors in the nucleus of the solitary tract and ventrolateral medulla reflect important roles of Ang II in cardiovascular control. In the periphery,

Figure 1 The renin-angiotensin system.

AT₁ receptors occur in high levels in the zona glomerulosa of the adrenal cortex and adrenal medulla. In the kidney, AT₁ receptors occur in glomeruli, proximal tubule, and medullary interstitial cells. AT₁ receptors occur on vascular smooth muscle cells and in the conduction system and vagal ganglia of the heart.

The antagonists losartan and candesartan are AT₁ selective and are used clinically to treat hypertension and cardiovascular disease.

AT₂ Receptor

The function and characteristics of the AT₂ receptor are less well understood. While it is also a seven transmembrane receptor, it shares only 34% homology with the AT₁ receptor. The signaling mechanisms are distinct from the AT₁ receptor and include stimulation of tyrosine or serine/threonine phosphatases, which inactivate MAP kinases, and potassium channel activation. AT₂ receptor stimulation may inhibit growth and promote apoptosis, thereby opposing actions at the AT₁ receptor.

The AT₂ receptor is highly expressed during fetal development and rapidly declines at birth. In the adult brain, AT₂ receptors are constrained to the molecular layer of the cerebellum, thalamus, and superior colliculus. In neurons, AT₂ receptor activation may result in hyperpolarization and decreased excitability via enhanced K⁺ channel activity. In the periphery, it is found within the adrenal medulla, cardiac fibroblasts, and the non-pregnant uterus. Expression of the AT₂ receptor is upregulated in pathological conditions such as heart failure, renal

failure, vascular injury, and wound healing. AT₂ receptor stimulation also induces vasodilation mediated by bradykinin, nitric oxide, and cyclic GMP. The AT₂ receptor also binds directly to the AT₁ receptor, and may antagonize its function via this heterodimerization.

The AT₂ receptor is selectively inhibited by the nonpeptide compound PD 123319 while the peptide analog CGP 42112A acts as a partial agonist.

AT₄ Receptor

The hexapeptide fragment of angiotensin (3–8) (Ang IV) has actions distinct from Ang II and binds to a novel binding site distinct from the AT₁ and AT₂ receptors. The AT₄ receptor is a type II integral membrane protein identical to the insulin-regulated aminopeptidase (IRAP), a zinc metallopeptidase of the M1 family that translocates rapidly to the cell surface after insulin stimulation.

The AT₄/IRAP receptor occurs abundantly in the brain within the neocortex, CA1 to CA3 regions of the hippocampus and motor nuclei, where it is closely associated with cholinergic neurons, consistent with the memory-enhancing properties of Ang IV. In the periphery, it is found in blood vessels, cortex, and outer stripe of the outer medulla of the kidney and adrenal medulla and cortex. Its main peripheral physiological effect is vasodilation.

Two N-terminally modified analogs of Ang IV have high affinities for the AT₄ receptor: Nle¹-Ang IV and norleucinal Ang IV and exhibit agonist properties along with a structurally distinct peptide, LVV-hemorphin 7.

Ang 1–7 Receptor

A possible role for Ang 1–7 as a cardioprotective peptide with vasodilator, diuretic, and antiproliferative effects has recently been suggested. The Ang 1–7 receptor may be the G-protein-coupled receptor Mas, encoded by the Mas1 proto-oncogene.

Actions of Angiotensin**Fluid and Electrolyte Balance**

Ang II rapidly induces drinking, whether administered peripherally, where it acts on AT₁ receptors within the circumventricular organs, or centrally, where the lamina terminalis encompassing the median preoptic nucleus is the principal site of action.

Centrally administered Ang II also stimulates salt appetite. This action is blocked by centrally administered AT₁ and AT₂ receptor antagonists; however, the central sites of action of Ang II-induced salt appetite have yet to be determined. Mineralocorticoids have a major influence over this stimulus and are believed to have a concomitant action with the RAS in initiating salt appetite.

Blood Pressure Regulation

Infusion of Ang II into the periphery or brain raises blood pressure. Peripheral administration of Ang II increases arterial pressure via increased vascular resistance, a consequence of both direct action on vascular smooth muscle and central actions resulting in activation of the sympathetic nervous system and stimulation of vasopressin release.

In a genetic animal model, the spontaneous hypertensive rat (SHR), the brain Ang II system is overactive. Higher levels of Ang II and angiotensin receptors have been observed, and the SHR exhibits an exaggerated pressor response to central Ang II.

Hormone Release

Ang II has several roles as a neuropeptide. Central infusion of Ang II is a potent stimulant for the release of vasopressin. Ang II may also participate in cyclic regulation of reproductive hormones. Plasma Ang II is raised in the luteal phase of the menstrual cycle, and administered Ang II elevates plasma levels of luteinizing hormone during this phase.

Behavior

The RAS, either acting directly or through the modulation of various neurotransmitters, has been implicated in a range of behavioral and cognitive processes. While there is conflicting evidence of the role of Ang II in memory and learning, it is clear that

central infusions of Ang IV facilitate memory retention and retrieval in rats. Ang IV promotes learning in passive avoidance and spatial memory tasks, and reverses memory deficits induced by scopolamine-induced amnesia and bilateral perforant pathway lesions. The mechanisms of how AT₄ ligands mediate their effects are unclear, but may involve interactions with brain cholinergic systems, modulation of neural glucose metabolism, or inhibition of neuropeptide metabolism by IRAP.

Pathophysiology of the RAS

The local tissue RAS has important effects on the pathological changes of organ structure that are mediated by altered modulated gene expression, growth, fibrosis, and the inflammatory response.

Hypertension

The RAS regulates blood pressure, and inhibitors of the system have important therapeutic actions in treating hypertension. ACE inhibitors are widely used in hypertension and cardiovascular and renal disorders. AT₁ antagonists, such as losartan and candesartan, are increasingly used in hypertension and are well tolerated.

Cardiac Hypertrophy

Cardiac hypertrophy is characterized by increased deposition of extracellular matrix (ECM) constituents, proliferation of cardiac fibroblasts, and hypertrophic growth of cardiac myocytes, which alter the contractile properties of the heart.

The RAS is a key mediator of cardiac adaptations to hemodynamic overload. Ang II directly induces cellular responses in myocardial cells. In cultured cardiac fibroblasts, Ang II stimulates fibroblast proliferation, collagen synthesis, and the expression of ECM proteins such as fibronectin via activation of the AT₁ receptor. In cardiac myocytes, Ang II exerts a direct growth-promoting effect on only neonatal cells, and thus may act indirectly by inducing the expression of growth factors such as TGF- β_1 .

Both clinical and experimental studies demonstrate a favorable impact of AT₁ antagonists and ACE inhibitor therapy on the progressive remodeling and ventricular dysfunction of cardiac hypertrophy by reducing the action of Ang II. In addition, the beneficial effect of ACE inhibition might be related to local accumulation of bradykinin.

Microvascular Injury

Kidney Both ACE inhibitors and AT₁ antagonists exert protective effects in chronic renal disease by

improving glomerular filtration, preventing glomerular and tubulointerstitial toxicity of ultrafiltered proteins, and limiting the direct nephrotoxic effects of Ang II, especially in diabetes.

Eye Neovascularization in the retina of diabetic patients is a major cause of visual loss. There is a large body of evidence for a local RAS within the eye that is activated in diabetes. This appears to be directly responsible for an increase in vascular endothelial growth factor (VEGF) that is implicated in the pathogenesis of diabetic retinopathy. Inhibition of ACE appears to reduce concentrations of VEGF, with a concurrent antiproliferative effect independent of systemic VEGF levels or blood pressure. AT₁ receptor blockade has been shown to reduce neovascularization independent of VEGF levels in animal models. This may be due to antagonism of activation of MAP kinase, which is a potent cellular proliferation stimulator, by Ang II.

Brain Circulating and locally formed Ang II controls cerebral blood flow by AT₁ receptor stimulation in cerebral vessels and sympathetic nerves. The Perindopril Protection against Recurrent Stroke Study (PROGRESS) has shown that ACE inhibitor therapy combined with diuretics can decrease recurrence of stroke by 44% in hypertensive patients and by 42% in nonhypertensive patients. Chronic AT₁ blockade inhibits brain and cerebral artery AT₁ receptor and reduces cortical ischemia and tissue swelling produced by middle cerebral artery occlusion with reperfusion.

Atherosclerosis

Ang II plays a critical role in the initiation and progression of atherosclerosis via promotion of superoxide production and acting as a pro-inflammatory molecule, with resultant local inflammation and tissue damage. Treatment with ACE inhibitors or AT₁ antagonists may slow progression of atherosclerosis. This is in part associated with decreased expression of inflammatory mediators and improved endothelial function.

The RAS and Stress

Both brain and peripheral Ang II participate in the stress response. In response to stress, AT₁ receptor expression increases in the hypothalamic paraventricular nucleus and median eminence, key sites controlling the hypothalamic-pituitary-adrenal (HPA) axis. Concurrently, there is increased synthesis and release of corticotropin-releasing factor (CRF) from the median eminence and adrenocorticotrophic hormone (ACTH) from the anterior pituitary and consequently adrenal glucocorticoid responses (Figure 2). Associated with this are central actions that contribute to enhanced peripheral sympathetic activity.

The increase in sympathetic stimulation leads to enhanced renin release, increased circulating Ang II, and, consequently, fluid retention and vasoconstriction, with increased blood pressure and heart rate.

The RAS has been implicated in a number of experimental models of stress. Restraint stress in rats

Figure 2 Angiotensin II and the stress response.

increases AT₁ receptor levels in the hypothalamic paraventricular nucleus, SFO, and median eminence, consistent with roles in HPA activation. Concurrent changes in Ang II receptor number in the anterior pituitary and adrenal zona glomerulosa and medulla parallel the peripheral influences of the RAS on the HPA axis. Isolation stress enhances brain Ang II receptor numbers, which can be suppressed by AT₁ receptor antagonists. Conversely, central AT₁ receptor antagonism attenuates stress-induced sympathetic nervous and adrenomedullary responses.

The SHR is more susceptible to stress than normotensive Wistar-Kyoto (WKY) rats, and has an overactive central RAS. Differential expression of AT_{1A}: AT_{1B} receptors is observed in the HPA of SHR, and Ang II produces an exaggerated response of ACTH and corticosterone.

Human Stress Disorders
Stress Responses
Animal Models
Summary

Glossary

- Acute stress** Changes in physiology and behavior that occur during and shortly after exposure to a stressor.
- Chronic stress** Changes in physiology and behavior that persist for days or weeks during repeated stressors or after exposure to a stressor or stressors.
- Posttraumatic stress disorder** A psychological disorder that follows exposure to a traumatic event and is characterized by intrusive imagery, sleep disturbances and nightmares, poor concentration and memory, hypervigilance, and numbness.

Stressor A change in the environment that is sensed by an organism, is aversive or potentially harmful to that organism, and elicits acute and/or chronic stress responses.

An organism undergoes a series of physiological changes when exposed to a stressor. In the short term, several brain centers can be activated, including, among others, the locus coeruleus in the brain stem, the paraventricular nucleus in the hypothalamus, and amygdala and hippocampus in the limbic system. The activation of these centers leads to increased sympathetic nervous system (SNS) activity and elevated hypothalamic-pituitary-adrenocortical (HPA) axis hormones. These responses are homeostatic mechanisms that allow an individual to cope with a stressor and eventually turn off the stress response through negative feedback. However, if people are exposed to a very severe or prolonged stressor, more persistent changes characteristic of posttraumatic stress disorder or a general stress reaction can become established. Animal models of stress have been used to study these and other facets of acute and chronic stress responses.

Human Stress Disorders

Posttraumatic stress disorder is the only chronic stress disorder recognized in the *Diagnostic and Statistical Manual of Mental Disorders* published by the American Psychiatric Association, but it is grouped with anxiety and panic disorders, which are characterized by acute stress responses. Stress can also contribute to depressive disorders. In addition, a number of medical conditions result from stress. It is well recognized that stress is linked to cardiovascular disease, particularly hypertension and sudden cardiac death. Stress can also suppress immune function, leading to susceptibility to infections. In some abused children, stress can produce growth hormone deficiency and small stature. Stress and excessive exercise in women can interfere with ovarian cyclicity and fertility. These are only a few examples of the ways stress directly affects health through its actions on diverse systems within the body.

Stress Responses

Neuroendocrine and Immune Responses

Stress affects a number of physiological systems whose regulatory mechanisms interact, and corticotropin-releasing hormone (CRH) appears to have an important integrative function. In the brain stem, increased CRH

is required for normal SNS activation by stress. In the hypothalamus, CRH increases with stress and its secretion leads to release of adrenocorticotropin by the pituitary gland, which in turn stimulates the adrenal cortex to secrete glucocorticoids. Although its exact function remains unclear, CRH is also present in the limbic system. Thus, CRH appears to have a central role in coordinating the major responses to stress.

The catecholamines, epinephrine, and norepinephrine also play a critical role in the stress response. Plasma epinephrine comes from the adrenal medulla and is more responsive to psychological stressors, whereas plasma norepinephrine comes largely from the sympathetic nerve terminals and is more responsive to physical stressors. In addition to increasing the heart rate and blood pressure during stress, the catecholamines stimulate the breakdown of glycogen and fats to increase the availability of energy for the brain and muscles.

Almost all endocrine systems respond to stress in one way or another. Depending on the duration, intensity, and nature of the stressor, plasma prolactin and vasopressin can be elevated and growth hormone can be suppressed or stimulated. The hypothalamic-pituitary-thyroid and hypothalamic-pituitary-reproductive axes are generally suppressed by stress. In addition, plasma insulin usually decreases and glucagon increases.

These endocrine changes can be related to changes in immune function. Infection activates a number of cytokines that induce fever, stimulate the HPA axis, and inhibit the reproductive axes. In addition, the glucocorticoids can inhibit immune function, and a number of the other hormones have immunomodulatory roles. Thus, the interactions between the endocrine and immune systems in response to stress are bidirectional.

Psychological Responses

Exposure to stressors can result in posttraumatic stress disorder, and the stress response is a major component of anxiety disorders and phobias. Stress can also significantly impact cognitive function by impairing or enhancing it depending on the stressor and the type of learning or memory being assessed. In addition to these effects of stress, a number of psychological processes including habituation and sensitization, predictability, controllability, and coping can modify the responses to stressors.

There is a coordinated response to a stressor by most systems in the body that allows an individual to cope with the stressor and restore baseline conditions after the stressor has ended. One of the primary concerns when evaluating animal models of stress is what features of the stress response are important to judge the validity of the models. From the discussion

so far, it is clear that this will depend on the organ system being studied and the stressors being modeled. For example, many researchers use animal models involving psychological stress because they argue that most human stressors are primarily psychological or have a large psychological component, but common physical stressors in people are often overlooked, including, among others, disease and infection, exercise, childbirth, surgery, and physical trauma during even minor accidents (broken bones, cuts, strains, and burns). An example of having to consider the organ system being studied is research into the effects of cardiovascular stress that has often used dogs, rabbits, and pigs rather than rodents because the cardiovascular systems of the former are more like those of humans. Thus, there are many valid animal models of human stress directed toward understanding different facets of the stress response.

Animal Models

The endocrine, immune, and behavioral responses to stressors have been studied most often using rodents in which the neural, endocrine, and immune substrates involved in the stress response have been delineated. However, a lot of applied stress research in animal husbandry is overlooked; the effects of stress on reproduction, weight gain, and health have often been studied in commercially important species. Finally, as previously noted, cardiovascular responses to stress have often been studied in rabbits, dogs, and pigs because of subtle differences between people and rodents in cardiovascular regulation.

Acute Stress

Physical stressors Most studies of acute responses to a variety of stressors have been carried out in rodents. Commonly used acute stressors include restraint, shock, swimming, cold, loud noises, novelty, and social conflict. These stressors can be applied for periods as short as 1–2 min or as long as 6–8 h. The acute response to these stressors may be followed during the stressor and for several hours after the stressor has ended. It is clear that most, if not all, of these stressors have substantial short-term effects on behavior, physiology, and immune function. It is commonly thought that the acute stress response is self-limiting because the responding systems are adaptive and negative feedback loops will terminate the responses. Failure to terminate the acute stress response appropriately can lead to persistent changes that are characteristic of a chronic stress state.

Most of these acute stressors are applied in sessions during which the animals must be removed from their

home cages, which in itself is a mild stressor. Thus, the stressors also include a novelty component involving removal from the home cage and handling. In order to isolate the effects of a particular stressor, sometimes the stressed animals are compared with controls that have been removed from their cages and put in a novel environment, whereas other times all the animals are handled 1–2 weeks before exposure to the stressor in order to habituate them to handling and novelty.

Restraint stressor protocols are described in another entry in this encyclopedia (see **Restraint Stress**). Electrical shock as a stressor has been used mostly in rodents and includes both foot shock and tail shock. One of the advantages of shock is that stressor intensity can be graded monotonically while duration and other parameters are held constant. With the other stressors listed, it is more difficult to manipulate and assess stressor intensity and to prevent the confounding effects of stressor duration. Foot shock is administered in Skinner boxes with electrified grids on the floor, and the animals are freely moving. Tail shock is administered to restrained animals through electrodes attached to the tail. One advantage of foot shock is that animals are freely moving, but this also creates a problem because they can learn to reduce the amount of shock they receive by assuming particular stances on the grid. Tail shock permits us to administer uncontrollable, inescapable shock, to ensure the delivery of the same amount of shock to each rat, and to verify the intensity of each shock.

Swim stressors are now used more frequently in rodents because Animal Welfare Committees are increasingly reluctant to approve shock stressors. The rodents are placed in a container of water for 5–30 min with either running water or a weight to prevent floating. The intensity of stress is manipulated by the duration of the swimming and the temperature of the water; the colder the water, the more intense the stressor. Swimming is a compound stressor with an exercise or exertion component and an aversive component involving cold temperatures and being wet. Exposure to cold alone, without swimming, is also used as a stressor. However, when repeated or long-term cold exposure is used, there are physiological adaptations to low temperatures that may be independent of stress responses and confound the interpretation of findings; for example, the thyroid hormone axis is generally suppressed by stressors but stimulated by long-term exposure to cold. Finally, loud noises around 120 dB have been used as stressors, but some species will rapidly adapt during a session of repeated or continuous exposures to this level of sound.

Psychological stressors There are also acute stressors that are thought to produce more psychological than physical stress, such as novelty and a variety of social stressors. Novelty stressors can entail simply moving the home cage to a different room, transferring the animal to a bare cage or a cage with unused bedding, or exposing the animal to unfamiliar objects. These stressors are listed in the order that is generally thought to reflect increasing stressor intensity. Some acute social stressors that have been used include exposure to predators, exposure to conspecifics in species with dominance hierarchies, and exposure to pheromones from more dominant conspecifics. Finally, the division of stressors into physical and psychological is mostly heuristic in that all physical stressors clearly have a major psychological component and psychological stressors often have a physical component, as when some fighting is allowed between conspecifics in social conflict paradigms. Conversely, it has been shown that anticipation of physical stressors, such as shock or immobilization, imparts a strong psychological component to these stressors.

Nonstressed controls In using animal models of stress, it is important to select appropriate control groups. If the stress effect is small or we are studying complex interactions between stress and other factors, it is important to provide the most stress-free environment for the control animals. Animals in stress studies are often maintained in large vivariums without an appreciation of the stressfulness of this housing. Loud noises in general and particularly during animal care, handling during cage changes, and other experimenters working in the same room often lead to elevated stress hormones in control rats. In addition, data collection must be as stress-free as possible, for example, either very rapid or through indwelling catheters to ensure basal hormone levels in controls. It may also be important to house non-stressed controls apart from stressed animals because stressed rats may bring back stress-specific odors to their home cages.

Acute stress responses and stressor intensity The acute stress response is characterized by the changes in the endocrine systems previously described. One critical question in experimental models is how to evaluate and compare the stressfulness of different stressors. One possibility is to study responses to a graded series of stressor intensities and determine which stress-responsive systems respond in a monotonic way to increasing stressor intensity. For example, one study has shown that acute prolactin responses to foot shock are a better index of stressfulness than

adrenocortical hormones or catecholamines because the responses of the latter are not as well graded; that is, they tend to be all-or-nothing types of responses.

Chronic Stress

Chronic stressors Commonly used chronic stressors include repeated exposures to the acute stressors previously listed, continuous performance tasks, overcrowding, and complex social situations when appropriate for the species. Repeated exposures to the same stressor can lead to habituation, that is, smaller responses over time and eventually no response to the stressor. Two approaches have been used to prevent this habituation. In the first, different acute stressors are alternated on consecutive days. The second approach uses relatively few exposures to a very intense stressor that prevents habituation and may actually produce sensitization, that is, larger responses to the stressor over time. Whether habituation or sensitization occurs can be related to the intensity of the stressor inasmuch as animals will habituate to low-intensity shock stress and sensitize to the same shock stress at higher intensities.

Continuous performance tasks are generally operant tasks that require frequent responses to avoid aversive stimuli or, in a few cases, to obtain positive reinforcement. Frequent motor responses are one aspect of this stressor, but another is the requirement for frequent or continuous attentiveness over days. Increasing the number of animals (three or more) in a cage is stressful, but so is single housing of social species. Finally, several chronic stress models involve the daily changing of cagemates in species with dominance hierarchies, which leads to the continual disruption of and need to reestablish the hierarchies. Most recently, a few laboratories have added naturalistic environments to the disruption of dominance hierarchies and social interactions. In these chronic social stressors, rank in the hierarchy usually determines stressfulness with more dominant individuals generally showing less stress.

Finally, there is an extensive literature on two other specific animal stress models: learned helplessness and fear conditioning. The learned helplessness paradigm was used in the past as a model to understand the physiological underpinnings of depression and to screen compounds for antidepressant activity. In this model, an animal was first exposed to inescapable shock, and then it failed to escape subsequent shock when given the opportunity. Antidepressants will reverse this failure to escape, and so the paradigm was used to screen novel compounds for antidepressant activity. More recently, inescapable stress without the

helpless behavior has been used for animal models of depression.

Another model of psychological stress is fear-conditioned behavior. In these models, an animal is stressed in a particular context and later returned to the context without the stressor. On reexposure to the context, the animal becomes hyperresponsive, which may be manifested in fear-potentiated startle, freezing behavior, or elevated stress hormones (e.g., glucocorticoids).

Chronic stress responses The chronic stress state is characterized by persistent changes in physiology and behavior that last beyond the time when the acute stress response should have dissipated. Posttraumatic stress disorder is such a state whose effects can last for years or decades after the precipitating traumatic stressor. In animals, most persistent stressor effects are followed for days or weeks, although there are neonatal stress regimens whose effects have been reported to last throughout the life of the animal. It remains unclear how physiological systems that constantly adapt to changes in the environment maintain a new set point for a such long time after some stressful situations. For example, the plasma glucocorticoid response to an acute stressor is well understood; a multilevel, negative feedback system returns glucocorticoid levels to baseline 1–3 h after most stressors. However, baseline glucocorticoid levels can remain elevated for 3–5 days after repeated exposure of rats to tail shock. It is unclear whether this is due to persistently increased activity in the stress-mediating areas of the brain leading to increased CRH release or persistent changes within the HPA axis itself that are only reversed after several days.

Most animal models of chronic stress are characterized by persistent neuroendocrine, immunological, and behavioral changes. The entire HPA axis is activated, the thyroid and reproductive axes are suppressed, growth hormone is suppressed, and prolactin is stimulated. Most studies report immune suppression after chronic stress, but there can be enhanced immune function; for example, chronic stress will exacerbate pathology in experimental allergic encephalomyelitis, an autoimmune animal model for multiple sclerosis. The behavioral changes that are usually seen include hyperarousal indicated by increased startle responses and fear of novelty indicated by decreased exploration in an open field. In addition, chronic stress can inhibit spatial memory in the Morris Water Maze, but it can enhance the acquisition of a classically conditioned eye-blink response. Thus, the effects on learning and memory may depend on the kind of stressor and the type of learning being tested.

Psychological modifiers In addition to these behavioral effects of stressors, a number of psychological variables will affect the stress response. In most studies, the ability or perception of the ability to control the occurrence of stressors produces smaller stress responses. In these studies, one animal has control of stressor presentation and a second is yoked so that it receives the same stressors but without control; yoked animals show larger responses. The ability to perform coping or escape responses during stressors also has a major role in determining stressfulness; animals permitted coping reactions or escape responses show smaller stress responses than those that are not. The predictability of a stressor can also be manipulated so an animal can anticipate an upcoming stressor. In most experiments, unpredictable stressors result in greater responses, but one study of rats exposed to stressors in their home environment showed that predictable stress can lead to increased chronic stress responses.

Summary

This short description of animal models for human stress cannot be comprehensive because so many different types of stressors are used, the effects even with the same stressor are often dependent on the particular stress paradigm, and there are important differences among animal species in their responses to particular stressors. Instead, this article illustrates the wide range of stressors that have been used and the diversity of the stress respondents that have been studied. When studying stress, it is important to remember that many, if not all, of the stress-responsive systems are reacting to a stressor even if the experimenter is measuring only one respondent. Finally, animal models of stress have been critical in understanding how the human body responds to stress, what the health consequences of those responses are, and what therapies can be used to treat stress.

Glossary

Host defense system

A complex system that enables the organism to defend itself from tissue injury, inflammation, or infection by innate (natural) and acquired (specific) mechanisms.

Signal sequence

An N-terminal hydrophobic amino acid sequence that directs newly translated proteins to the Golgi apparatus for packaging into secretory vesicles, post-translational processing, and release by exocytosis.

Glucocorticoids (GCs) exert diverse actions in the body, which are required for the maintenance of homeostasis. Their complex effects are mediated mainly by mechanisms involving the induction or repression

of key target genes. Lipocortin 1 is the product of one such gene; it fulfills a prominent role in effecting the regulatory actions of the steroids in the host defense and neuroendocrine systems.

Structure of Lipocortin 1

Lipocortin 1 (LC1, annexin 1) is a 37-kDa member of the annexin superfamily of Ca^{2+} and phospholipid-binding proteins. Annexins are found in a wide range of organisms (vertebrate, invertebrate, and plant) and are characterized structurally by a highly homologous core domain that normally comprises a fourfold repeat of 70 amino acids and enables the proteins to bind Ca^{2+} and negatively charged phospholipids. The core is attached to the N-terminal domain, which is unique in length and sequence for each member of the family; this domain confers the biological specificity of the individual annexins and thus enables the proteins to exert distinct and specific actions on their target cells. **Figure 1** illustrates the primary structure of LC1; note that the N-terminal domain includes potential sites for phosphorylation, glycosylation, and protease action. LC1 is encoded by a single gene in mammals and in the chicken, but two LC1 genes have been identified in the pigeon. The rat, mouse, and human genes show a high degree of homology; each comprises 13 exons, the first of which is non-coding (**Figure 1**), but no spliced variants have been described to date. A TATA motif 30 bp upstream of the transcription start site is consistent with an inducible and tissue-specific mode of regulation. However, the promoter region of the mammalian gene is characterized poorly, although potential response elements for GCs, activating enhancer binding

protein (AP)-1, Oct-1, cAMP, and serum have been identified.

Distribution of Lipocortin 1

LC1 is found in many organs and tissues of the body, but is often localized in discrete populations of differentiated cells, particularly epithelia. It is particularly abundant in the lung, thymus, spleen, placenta, and seminal fluid. In addition, many cells involved in the inflammatory response (e.g., macrophages, polymorphonuclear neutrophils, and monocytes) express very substantial amounts of LC1, as do cells of the neuroendocrine system. Within the pituitary gland LC1 is expressed mainly by nonsecretory folliculostellate cells but also by endocrine cells, whereas in the hypothalamus it is expressed most strongly in the median eminence and paraventricular nucleus (i.e., areas associated with the regulation of anterior pituitary function). LC1 is also expressed in lesser amounts elsewhere in the brain where it appears to be confined mainly to microglial cells, although some neuronal expression may also occur.

The subcellular distribution of LC1 is unusual; it is abundant in the cytoplasm, but a small proportion is also found on the external surface of the cell membrane, where it attaches via a Ca^{2+} -dependent linkage to binding proteins. LC1 also binds to the inner leaflet of the plasma membrane, and cell fractionation studies have identified an integral membrane pool of LC1.

Regulation of the Expression and Cellular Disposition of Lipocortin 1

Glucocorticoids

LC1 was first identified as a GC-inducible protein in extracts of conditioned media from rat peritoneal macrophages. Subsequent studies showed that the expression of LC1 mRNA and protein in experimental

animals is reduced substantially by adrenalectomy but that it is restored by maintenance doses of GCs. The administration of the GC-receptor antagonist mifepristone (RU486) also lowers the resting LC1 levels in rodents, thus confirming a role for the steroids in the regulation of LC1 expression.

In addition to inducing the synthesis of LC1, GCs also modify the cellular disposition of the protein in such a way that intracellular (cytoplasmic) LC1 is exported to the outer surface of the cell. This process of exportation, termed externalization, is likely to be an important facet of LC1 biology because it enables the protein to reach specific binding sites on the outer surface of cells that appear to be critical to its action. Externalization is normally evident within 0.5–2 h of the steroid challenge and involves the passage of both preformed and newly synthesized LC1 across the membrane. Intracellular (cytoplasmic) stores of the protein may fall initially, but, ultimately, the positive effects of the steroid on LC1 synthesis exceed the effects on exportation and thus the depleted stores are replenished. The effects of GCs on the synthesis and cellular disposition of LC1 are specific, and other steroids (androgens, estrogens, progestogens, mineralocorticoids, and cholesterol) are without effect.

The mechanism by which LC1 crosses the membrane is unclear, but it is unlikely to involve exocytosis. LC1 is a polar molecule and, although its sequence includes some short hydrophobic regions, it lacks a classical signal sequence required for entry to the vesicular packaging system. Moreover, drugs that block the classical endoplasmic reticulum–Golgi pathway of protein secretion do not affect the cellular exportation of LC1.

Other Factors

Several factors other than GCs are implicated in the regulation of LC1 expression, including interleukin 6 (IL-6) and phorbol esters, which exert positive

influences. The apparently complementary action of IL-6 and the steroids is interesting because there are other examples of these substances acting cooperatively, for example, in the generation of acute-phase proteins in the liver. LC1 in the brain is upregulated readily by tissue injury and excitotoxins, such as the excitatory amino acids glutamate or kainate, but the underlying mechanisms are unknown.

Functions of Lipocortin 1

Control of Inflammation

LC1 exhibits significant anti-inflammatory activity in a number of experimental models of inflammation and is now believed to serve as an endogenous regulator of the inflammatory response. In accord with this view, the passive immunization of animals with neutralizing antisera against LC1 quenches the ability of GCs to suppress edema formation and neutrophil migration in several models of inflammation; it also exacerbates brain damage caused by middle cerebral artery occlusion in a rat model of stroke. Conversely, human recombinant LC1 (hu-r-LC1) and peptides derived from it have beneficial effects in several models of inflammation. Interestingly, autoantibodies to LC1 have been identified in the plasma of some patients with chronic inflammatory disease, such as rheumatoid arthritis and systemic lupus erythematosus. Moreover, there is evidence of a causal relationship between the antibody titers and the incidence of certain types of steroid resistance, particularly in cases in which higher doses of steroid are still able to repress the symptoms of the disease. However, not all the anti-inflammatory actions of GCs can be attributed to LC1 and, in some instances, GCs are effective but LC1 is not; for example, steroids inhibit the generation of both carrageenin- and histamine-induced paw edema in the rat, but LC1 is effective only against carrageenin.

Some of the anti-inflammatory actions of LC1 are almost certainly explained by the ability of the protein to prevent the generation of proinflammatory eicosanoids, but others, such as the inhibition of IL-1- or IL-8-induced leukocyte migration, cannot be accounted for in this way. Early work in the field suggested that LC1 blocks the release of arachidonic acid from membrane phospholipids by inhibiting the enzyme phospholipase A2 (PLA2). Later data, however, refuted this view and, although there is good evidence that the inhibition of arachidonic acid release induced by LC1 is secondary to a reduction in cPLA2 activity, the exact mechanism involved remains to be determined; an effect on a signal transduction cascade upstream of the enzyme is a distinct possibility.

Lipocortin 1 and the Neuroendocrine System

LC1 fulfills a significant role as a mediator of GC action in the hypothalamic-pituitary-adrenocortical (HPA) axis, acting mainly at the levels of the hypothalamus and anterior pituitary gland but also possibly at other sites in the brain (e.g., the hippocampus) to effect the negative feedback actions of the steroids on the axis. *In vivo* central or peripheral administration of anti-LC1 antisera effectively negates the ability of GCs (corticosterone or dexamethasone) to block the overt increases in adrenocorticotrophic hormone (ACTH) secretion induced by IL-1 β , whereas central injections of hu-r-LC1 abolish the rises in GC secretion induced by either IL-1 β or IL-6. Similarly, the inhibitory actions of GCs on the evoked release of the corticotropin releasing hormone (CRH) from the hypothalamus and ACTH from the anterior pituitary gland *in vitro* are mimicked by hu-r-LC1 and are reversed specifically by anti-LC1 antisera and LC1 antisense oligodeoxynucleotides (ODNs) directed against sequences specific to the LC1 gene.

LC1 also contributes to other aspects of GC action within the neuroendocrine system. In particular, it acts at the pituitary level to mediate the inhibitory actions of the steroids on the secretion of prolactin by the lactotrophs; in addition, it acts within the hypothalamus to mediate the acute stimulatory actions of the steroids on the secretion of GH.

Other Actions of Lipocortin 1

In addition to its effects on inflammatory responses and on the neuroendocrine system, LC1 may also contribute to other facets of GC action, including the manifestation of antipyresis, the suppression of growth and differentiation of some cells, and the modulation of the expression of some genes. In addition, like other annexins, LC1 has been implicated in the intracellular processes of vesicular fusion, particularly those concerned with endocytosis.

The suppressive actions of LC1 on cell growth have been studied most widely in A549 cells. This adenocarcinoma cell line requires prostaglandins for growth and, thus, when prostanoid production is inhibited (e.g., by administration of GCs or drugs that inhibit cyclo-oxygenase), cell growth is slowed or even halted. In contrast, cell growth is promoted readily by epidermal growth factor (EGF), which acts via a tyrosine kinase receptor to liberate prostanoids via a complex cascade involving the activation of cPLA2. The inhibitory effects of GCs on EGF-stimulated cell growth are associated with an increase in LC1 expression; moreover, the suppression of cell growth and prostanoid generation induced by the steroids are

mimicked by LC1 but reversed by exposure of the cells to anti-LC1 antisera or anti-LC1 ODNs. LC1 serves as a substrate for and is phosphorylated by the EGF receptor; it may thus produce its effects on cell growth and eicosanoid generation by disrupting the grb-, sos-, and mitogen-activated protein (MAP) kinase signaling cascade used by the EGF receptor to stimulate cPLA2 activity. However, the point at which LC1 disrupts this cascade remains to be defined.

The possibility that LC1 may contribute to the inhibitory effects of GCs on the expression of the inducible forms of cyclo-oxygenase (COX-2) and nitric oxide synthase (iNOS) has been investigated. COX-2 expression appears to be independent of LC1. However, in rat models of endotoxic shock, the ability of GCs to block the fatal hypotension that develops within hours of the administration of lipopolysaccharide is blocked by neutralizing anti-LC1 antisera, as is the expression of iNOS (assessed by western blot analysis or measurement of nitrate release), suggesting that LC1 is at least partially responsible for the downregulation of iNOS induced by the steroids. The molecular basis of this action is obscure, but it almost certainly involves the disruption of a key signal transduction system rather than a direct genomic action of LC1.

Lipocortin 1-Derived Peptides

An interesting and important discovery has been that at least some facets of the biological activity of LC1 can be attributed to sequences in the N-terminal of LC1 of the molecule. For example, a peptide comprising residues 2–26 (LC1_{Ac2-26}) has a profile of anti-inflammatory and antiproliferative activity similar to that of the full-length recombinant molecule, although it is approximately 200 times less potent. LC1_{Ac2-26} also mimics the effects of the full-length molecule on the neuroendocrine system, although again it is less potent. Shorter peptides may also be active. These peptides have the advantage that they are easier to work with than the full-length protein and inexpensive to produce; they thus provide valuable tools for research and may ultimately provide the base from which LC1 peptides or nonpeptide analogs may be developed for therapeutic use. The N-terminal peptides do not, however, mimic the effects of LC1 on vesicular aggregation; this property of LC1 requires the repeater sequences in the core and is thus likely to reflect the traditional Ca²⁺- and phospholipid-aggregating properties of the annexins.

Cell Surface-Binding Sites for Lipocortin 1

The preceding sections show that LC1 and the peptides derived from it mimic many of the diverse

regulatory effects of GCs within the host defense and neuroendocrine systems. However, they provide little insight into the mechanisms involved. Several lines of evidence suggest that at least some of the actions of the peptides may be exerted extracellularly, possibly via cell surface-binding sites. For example, the anti-LC1 antibodies that quench many of the actions of the steroids are unlikely to penetrate cells readily; moreover, the steroids themselves cause the cellular exportation of LC1. High-affinity saturable LC1-binding sites have been identified on the surface of a variety of cell types by fluorescence-activated cell (FAC) analysis, including human and rodent peripheral blood leukocytes, rat anterior pituitary cells, and various cell lines (e.g., the rat pituitary GH3 line). Confocal imaging has shown that the distribution of the surface-binding sites is punctate (discrete clumps) and variable; this is consistent with the widespread phenomenon of ligand-induced receptor clustering, a process that may be essential for internalization. The interaction of LC1 with the membrane cannot be explained merely by the binding of the protein to phospholipid because (1) it is abolished by mild trypsinization of the cells and (2) the ability of trypsinized cells to recover their capacity to bind LC1 in culture is prevented by the inclusion of the protein synthesis inhibitors cycloheximide and puromycin in the medium, thus suggesting a requirement for protein. Two candidate membrane proteins of molecular mass 15–18 kDa have been isolated from human monocytes. Their structure and function remain to be elucidated, but preliminary studies suggest that they are unlikely to be a classic seven-transmembrane-domain receptor and are more likely to be a protein involved in membrane organization and turnover.

What Is an Antibody Response?

Stress Proteins as Antigens

Stress and Antibody Response in Animals

Stress and Antibody Response in Humans

Stress, Antibodies, and Human Disease

Conclusions

Glossary

<i>Antibodies</i>	Proteins produced by B lymphocytes with the ability to bind specifically to molecular shapes.
<i>Antigens</i>	Molecular shapes, often on infectious agents or produced during infections, that can be recognized by antibodies and other immune receptors.
<i>Autoantibodies</i>	Antibodies able to bind to normal components of the body.
<i>B Lymphocytes</i>	Cells produced by the bone marrow and exported to secondary lymphoid organs where they are able to respond to antigens by producing antibodies specific to them.

<i>Immuno-globulins</i>	A synonym for antibodies. Different classes of immunoglobulins function in different ways. IgA is important in secretions, IgG and IgM are important in blood and other internal body fluids, and IgE is important in allergy.
<i>Stress proteins</i>	A family of molecules produced by cells and organisms under stress. These are sometimes called heat shock proteins and are highly conserved across many different organisms.
<i>T Lymphocytes</i>	Cells produced by the thymus and exported to secondary lymphoid organs where they are able to respond to antigens. A subset of T lymphocytes called helper cells (Th cells) assists B lymphocytes to produce antibodies.

What Is an Antibody Response?

Antibodies are produced as part of the immune system's behavior toward antigens of foreign material such as infectious agents like bacteria and viruses. They are soluble proteins that have the ability to bind specifically to shapes on particular antigens and to neutralize them or to lead to their inactivation and removal (see [Figure 1](#)).

Antibodies are produced by a class of lymphocytes called B lymphocytes that are derived from the bone marrow and active in secondary lymphoid organs such as lymph nodes, spleen, tonsils, and other gut-associated lymphoid organs. There are many millions of B lymphocytes in the body, but each B lymphocyte has the capacity to make antibodies with only one shape of antigen-binding site. In order to be activated to produce antibodies against a particular antigen, B lymphocytes must interact with antigens through specific cell surface receptors (see [Figure 2](#)) and usually also require assistance from a class of T lymphocytes (derived from the thymus) called helper T lymphocytes (Th cells). Some antigens, such as lipopolysaccharide (LPS) cell wall products of some

bacteria, can stimulate B lymphocytes to make antibodies without much in the way of T cell help and are called T-independent antigens.

Stress Proteins as Antigens

When cells or microorganisms are subjected to physical stresses such as changes in temperature or the composition of the medium in which they exist, they increase synthesis of stress proteins (or heat shock proteins). These stress proteins represent a highly conserved cellular defense mechanism mediated by multiple, distinct gene families that participate in many essential biochemical pathways of protein maturation and function during both times of stress and normal cellular homeostasis. They are thought to operate to protect the stressed cells by scavenging abnormal proteins and protecting newly synthesized proteins through a chaperone function. They are also strongly immunogenic and so play a prominent part in immune responses against microorganisms. For example, several protein antigens involved in antibody and other responses to mycobacteria have been identified as members of highly conserved heat shock protein families, suggesting that immune responses against microorganisms may be dominated by responses against the stress protein family. Furthermore, these highly immunogenic microbial stress proteins have very similar structures to stress proteins in human cells. Through this molecular mimicry, immune cross-reactions between microbial and human stress proteins may be involved in some chronic inflammatory and autoimmune disorders such as rheumatoid arthritis, ankylosing spondylitis, systemic lupus erythematosus, and inflammatory bowel diseases. Liaison between heat shock proteins and the immune response may therefore be both beneficial to the host as antigenic targets and detrimental to the host as promoters of autoimmunity. Psychological stress in infancy, associated with strain in families, for example, can be involved in the induction or progression of diabetes-related autoimmunity.

Figure 1 Antibodies interacting with specific antigenic shapes through their antigen-binding site.

Stress and Antibody Response in Animals

A considerable body of research has investigated the effects of stress on antibody responses in animals and, as summarized in [Table 1](#), a variety of factors have been found to be important.

When rats or mice are subjected to physical stressors such as restraint or exposure to coldness, the effect on antibody responses depends on whether the stressor is short- or long-term. For example, short periods of restraint stress (2 h over 2 consecutive days) enhance the primary antibody response to an

Figure 2 B lymphocytes in secondary lymphoid organs display surface immunoglobulins with antigen-binding specificity of the antibodies they are capable of producing when stimulated. Through these surface immunoglobulin receptors, antigens select appropriate B lymphocytes from the antigen-sensitive repertoire. Further activation signals come from helper T lymphocytes. The result is the proliferation of activated B lymphocytes and the production of antibody-forming cells and memory cells that are capable of responding more rapidly to antigens in future.

Table 1 Factors affecting the relationship between stress and antibody responses in animals

Types of stresses or stressors
Acute versus chronic stress
Controllability of stress
Social or psychological versus physical stressors
Activation of B lymphocytes versus synthesis of antibodies
Primary versus secondary antibody responses
Route of immunization
Timing and duration of stressor relative to antigen
Balance of neuroendocrine hormones
Season of the year

injected antigen in mice, while longer periods of restraint (6 h over 4 days) do not. The augmented response occurs in both immunoglobulin M (IgM) and IgG antibody classes. The effect is mediated at least in part by hormones from the adrenal cortex and can be blocked by α -adrenoceptor agonist drugs such as phentolamine and potentiated by β -adrenoceptor agonists such as propranolol. The temporal relationship between the stressor and antigen challenge is also important. Antibody responses are markedly suppressed in mice restrained before antigen injection but not significantly affected when the animals are stressed after immunization. Moreover, stresses in mice (such as restraint or social confrontation) diminish primary antibody responses but have little effect on secondary (or memory) responses.

An important group of hormones involved in stress-induced inhibition of antibody (and other) immune responses are the corticosteroids. These are produced by the cortex of the adrenal gland in response to stress-induced signals from the hypothalamus via the pituitary gland. Injection of the hypothalamic hormone corticotropin-releasing factor (CRF) into a rat 20 min before antigen administration diminishes both primary and secondary antibody responses, while CRF infusion 24 h after antigen does not affect antibody levels, suggesting that CRF (and corticosteroids) affect the initial induction phase of the antibody response. Corticosteroids have a direct inhibitory effect on B lymphocyte activation but also act on T cells to diminish helper activity. Conditions that lead to inhibition of antibody responses against T helper-dependent antigens often lead to enhanced responses against T-independent antigens, and adrenalectomy blocks both these effects by removing the gland that produces corticosteroids.

In addition to corticosteroids, two other types of hormone mediate stress effects on antibody responses. The pituitary hormone prolactin generally facilitates antibody responses and so acts as a balance to corticosteroid inhibitory effects. In addition, the pineal hormone melatonin counteracts many stress responses including antibody inhibition. In doing this, melatonin appears to act on Th cells to induce the release of opioid peptides with immuno-enhancing

properties. Melatonin and opioid effects therefore may come into play to effect immune recovery following corticosteroid-induced immune depression that results from stressful situations.

We cannot, however, consider the effects of stress on antibody responses simply in terms of enhancement or suppression because response kinetics can be different under stressed and nonstressed conditions. For example, in some studies, repeated cycles of physical restraint stress in mice delayed the development of antibodies to a virus infection but did not affect the ultimate magnitude or class of antibodies produced. Such a delay could nevertheless have consequences for the course of an infection and allow prolonged multiplication of an infectious agent, leading to the development of illness symptoms. A further factor affecting stress effects on antibody responses is the season of the year during which the stress occurs. In rats, unstressed animals display increased antibody responsiveness in spring and summer and decreased responsiveness in autumn and winter. This annual rhythm is accentuated in stressed animals and might therefore contribute to greater stress-induced susceptibility to infection during the winter months.

Although much animal experimentation has focused on physical stressors, social stress can also affect antibody responses in animals. For example, rats exposed to the odors of other stressed rats exhibit altered antibody responses as if they themselves had been stressed. Also, defeat associated with territorial defense affects a rat's ability to generate antibodies in response to an injected antigen. The more time such rats spend in submissive postures, the lower their antibody levels. Social status in monkeys also affects antibody-related factors. Low social status is associated with lower body weight, greater elevated cortisol responses to social reorganizations, and less aggressive behavior. Correspondingly, low-status monkeys have diminished immune responsiveness and a greater probability of being infected by upper respiratory tract viruses.

Clearly, a variety of factors mediate effects of stress on antibody production, but these effects occur as part of a bidirectional network of interactions between the immune system and the nervous system rather than a one-way, cause-effect process. This means that immune activity, or defects in immunity, can also influence the way animals behave. As an example, certain inbred strains of mice have a propensity to develop autoimmunity and produce high concentrations of antibodies against some of their own (self) antigens. In these mice, there is an association between high titers of autoantibodies and emotional behaviors resembling those of stressed animals. Disturbed emotional reactivity in these strains may

reflect the effect of autoimmunity on the hypothalamic-pituitary-adrenal axis, highlighting the bidirectional nature of the communication pathways between immune and nervous systems. The immune systems of animals given low doses of immunomodulatory drugs, such as cyclophosphamide, are subsequently more reactive to stress. This finding has implications for management of immunocompromised patients whose antibody responses may be excessively sensitive to stress-induced modulation.

Stress and Antibody Response in Humans

Investigations into the effects of stress on human antibody responses have tended to focus less on deliberately applied physical stressors (as in the animal experiments) and more on stressful situations in which people find themselves. Two particularly fruitful situations for this area have been students undergoing university examinations and people giving constant care to relatives suffering from chronic dementia. For example, when saliva samples from healthy students are compared a week before, 2 weeks after, and during examinations, antibodies normally present in saliva (the IgA class) are lower during the examination period. Moreover, the better a student's social support during the pre-exam period, the higher his or her salivary IgA during examinations. Although the psychologically perceived stress associated with examinations quickly diminishes after the examinations, the reduction of salivary IgA levels can persist for weeks. The stress of examinations is also associated with increased norepinephrine concentrations in saliva, particularly in students most aroused adrenergically by the examination. Antibody titers against Epstein-Barr virus (EBV) also increase during examination periods, indicating poorer immune control of latent virus reactivation.

IgA is the dominant antibody isotype not only in saliva but also on all mucosal surfaces where it acts as a first line of defense against microbial invasion. Because it is relatively noninvasive to measure, salivary IgA has been assessed in a variety of stressful situations aside from examinations. Similar to the conclusions from animal studies, it seems that in humans, some short-term stresses promote antibody production (at least in the saliva), while others, particularly longer-term stresses, depress it. For example, in one study, salivary IgA in professional soccer coaches was found to increase transiently during a match, while in another, nurses who reported more frequent episodes of anxiety had significantly lowered salivary IgA secretion rates. Such effects can be moderated by other factors, such as a sense of humor. Mild stress, as measured by the frequency of daily

hassles, correlates with diminished salivary IgA concentration, especially in people with low scores on a humor scale.

When salivary IgA is produced in response to challenge with a novel antigen, similar results are found. Following oral immunization, adults who report more desirable events on a day-to-day basis have higher concentrations of antigen-specific salivary IgA than when they report more undesirable events. Undesirable events appear to lower antibody levels primarily by increasing negative mood, whereas desirable events increase antibody levels by decreasing negative mood. These effects can be moderated by using coping skills such as deliberate relaxation. Significant increases in salivary IgA concentration occur in healthy volunteers after relaxation even though no change is observed in salivary corticosteroids.

Not only IgA antibodies but also IgG and IgM antibody classes in the blood are affected by stress. For example, in women immunized with a novel antigen, keyhole limpet hemocyanin, those reporting more stressful events in their lives tended to have lower baseline and 3-week postimmunization serum IgG antibody levels. In contrast, women reporting more good events tended to have higher IgG levels. Psychological distress scores correlated negatively and psychological well-being scores correlated positively with IgG antibody concentrations.

Similar effects are observed when people are immunized with more clinically relevant antigens such as hepatitis B vaccine. In one study, the antibody response of medical students given a series of three hepatitis B vaccinations around the time of major examinations depended on stress and anxiety levels. Those students who produced antihepatitis B antibodies after the first injection were significantly less stressed and anxious than those who did not. In addition, students who reported greater social support demonstrated higher titers of antibodies against hepatitis B antigens. Antibody responses to a variety of different vaccines, such as hepatitis B recombinant vaccine, meningococcal C conjugate vaccine, and influenza multiple subunit vaccine, have all been found to be diminished in people either living in highly stressful situations (e.g., caregivers for chronically ill relatives) or with high levels of daily perceived stress (measured through psychological stress questionnaires). Moreover, the detrimental effect of stress on the development and maintenance of antibody responses following vaccination can be alleviated by social support and by behavioral stress management interventions, suggesting that the context in which stressful events occur for a person is important in determining their effects on immune function. Also, the temporal relationship between perceived stresses

and their effects on antibody responses to vaccination is not straightforward. For example, in one study of healthy young adults given influenza vaccine, stress ratings on the 2 days before and on the day of vaccination were not associated with effects of antibody responsiveness, but stress during the 10 days following vaccine administration appeared to shape the long-term antibody response.

The context in which a stressful event occurs for a person is important in determining its effect on immune function. Events may be perceived as stressful, but if they have additional meaning or significance for the person undergoing them this may qualify their effects. For example, air traffic control is often considered to be a stressful occupation because of the intensity, responsibility, and unpredictability of the workload. Yet when psychophysiological stress reactions were assessed in air traffic controllers before and after each of two working sessions, the working sessions caused a marked increase in the concentration and secretion rate of salivary IgA, in contrast to the expected immunosuppressive effects. Corticosteroid but not salivary IgA levels were correlated with the amount of actual or perceived workload, indicating that positive emotional engagement rather than a negative stress effect may have been responsible for the observed changes.

The importance of context is also apparent from studies of emotional disclosure. When volunteers are asked to write anonymously and confidentially about traumatic events in their lives they generally report the process to be quite upsetting and stressful. If, however, through their writing they create a new relationship with the traumatic events, the effect on immune function appears supportive rather than inhibitory. This is exemplified by a study in which volunteers wrote about emotionally upsetting events every day for 4 days and then were immunized with hepatitis B vaccine. Compared with people in a control group who wrote about mundane topics, participants in the emotional expression group showed significantly higher antibody levels against hepatitis B antigens 4 and 6 months after their initial vaccination. Another study reported significantly lower EBV antibody titers (suggesting better cellular immune control over the latent virus) in people after a stressful emotional disclosure intervention.

By contrast, the stress of caring for a relative with progressive dementia such as Alzheimer's disease is a relatively hopeless chronic situation with little prospect of abatement. Following vaccination with an influenza virus vaccine, such caregivers exhibit a poorer anti-influenza antibody response and virus-specific T cell response compared with the control subjects, although, as discussed earlier, these effects

can be diminished by participation in stress management interventions. Greater impairment in the dementia victim is associated with greater depression and loneliness in caregivers. In 2001, in a critical review of the literature on psychological stress and antibody response to immunization in humans, Cohen and colleagues concluded that the evidence supporting an association between psychological stress and suppression of the antibody response is convincing for secondary responses but less impressive for primary responses. Since then, however, a number of studies have demonstrated reduced primary responses to vaccination, particularly in elderly people suffering high levels of chronic stress. Cohen and colleagues also concluded that health practices do not appear to mediate the relationship between stress and antibody responses to vaccination but that there are indications that elevated cortisol levels in stressed people may play a role.

Stress, Antibodies, and Human Disease

Extrapolating from the effects of stress on responses to vaccination, we might also expect there to be a relationship between stress and infectious disease in humans. A variety of studies show this to be so, particularly in the case of upper respiratory tract infections. Family functioning affects the frequency of influenza B infection, with indices of infection being significantly associated with both family cohesion and adaptability. This raises the possibility that family dysfunction may lead to altered immune responses, which in turn increase susceptibility to infection. A study of a large number of infants, children, adolescents, and young adults in a rural Caribbean village found that abnormal glucocorticoid response profiles, diminished immunity, and frequent illness were associated with unstable family or household conditions. Family relationships and concomitant stress and immunosuppression may therefore be important intermediary links between socioeconomic conditions and child health. In support of this, a study of preschool children observed that a subset of children (labeled as reactive) sustained higher illness rates under conditions of high family stress but lower rates in low-stress conditions.

Non-family-based stresses are also important in susceptibility to infections, as demonstrated by a series of studies from Sheldon Cohen and colleagues in which volunteers were asked to complete questionnaires about perceived stress before being intentionally inoculated intranasally with a cocktail of viruses associated with upper respiratory tract infections. Psychological stress was associated in a dose-response

manner with an increased risk of acute infectious respiratory illness following virus inoculation, and this risk was attributable to increased rates of infection rather than to an increased frequency of symptoms after infection.

Subsequently, Cohen and colleagues repeated the experiment with a new group of volunteers, but this time, in addition to the perceived stress questionnaire, they asked people to answer questions about their interpersonal and social support systems before they sprayed the virus concoction into their noses. Again, they observed a relationship between high levels of perceived stress and increased likelihood of infection, but additionally found the opposite relationship between social support and illness. Those people with more types of social ties were less susceptible to common colds, produced less mucus, were more effective in ciliary clearance of their nasal passages, and shed less virus. The presence of a diverse social network therefore buffers the potentially adverse effects of perceived stress with respect to susceptibility to infection. Further work is required to determine the role of virus-specific antibody responses in these effects.

Finally, autoimmune illnesses typically involve high titers of antibodies against various normal components of the body, and severity is usually correlated with autoantibody titer. There are reports that stress, depression, anxiety, and anger are associated with symptomatology in patients with various autoimmune illnesses, although to date, there has been little work directly linking stress, antibody levels, and illness severity. One study that has done so investigated antinuclear autoantibody titers in women and found a significantly higher incidence in women who had been sexually abused as children. These findings suggest that sexually abused girls may show evidence of an alteration in normal immune homeostatic function.

Conclusions

We have seen from the animal studies that stress affects antibody responses in different ways depending on the animal, the type and timing of the stressor, and its context. Some, but not all, of the effects appear to be mediated by the classical stress hormones of the hypothalamus-pituitary-adrenal axis. In order to make sense of the relationship between stress and antibody responses in humans, however, we must look beyond a purely biological or physical construction of the immune system and link its characteristics to psychological, social, and cultural processes. Kevin Ashbridge and Roger Booth have proposed that the immune system is engaged in the process of self-determination and therefore shares with the

neurological and psychological domains the goal of establishing and maintaining self-identity. From this perspective, the framework in which immune recognition occurs cannot be considered only as the context in which cells, receptors, and antigens operate, but as all the domains of life in which individuals define themselves. As a result, the meaning of events surrounding an antigenic stimulus (e.g., exposure to an infectious agent) is likely to condition the features of any observed antibody response. As discussed previously, this is particularly apparent in humans, in whom the effects of stressful events on antibody responses are dependent upon the context of meaning of those events.

Therapeutic Potential of CRF₁ Antagonists

Glossary

Adrenocorticotrophic hormone (ACTH, also known as adrenocorticotropin)
cLogP/cLogD

A hormone released into systemic circulation by the anterior pituitary as part of the hypothalamic-pituitary-adrenal (HPA)-stress response. ACTH induces the release of glucocorticoids from the adrenal cortex.

Calculated partition coefficients that express a compound's lipophilicity. A partition coefficient expresses the differential solubility of a compound in two solvents, with the log ratio of the concentrations of a neutral molecule partitioned between two solvents, classically octanol and water, called LogP. LogD expresses the partition coefficient at a specified pH, thereby accounting for charged forms of the molecule at a physiologically relevant pH (most typically that of blood, which has a pH of 7.4). Druglike substances have lipophilicities within a limited range, associated with favorable absorption, bioavailability, hydrophobic drug-receptor interactions, metabolism, and toxicity.

Corticotropin-releasing factor (CRF)

Isolated by Vale and colleagues in 1981, the first hypothalamic ACTH secretagogue to be identified. In addition to its hypothalamic endocrine function, extra-hypothalamic CRF is important in behavioral and autonomic stress responses.

Hypothalamic-pituitary-adrenal (HPA) axis

The neuroendocrine system which, during stress, amplifies a neural signal of physiological or psychological stress into a systemic, endocrine response. Hormones secreted as part of the HPA stress response cascade equip the organism to mobilize and utilize energy resources more effectively and, more generally, respond to the stressor.

Paralog

A gene (or gene product) related to a second gene (or gene product) by descent from an ancestral genetic duplication event. Although descended from common ancestral deoxyribonucleic acid (DNA) sequences, paralogs generally evolve new, distinct functions, though often related to that of the original sequence/gene product.

Pharmacophore

Term coined by Paul Ehrlich in 1909 as "a molecular framework that carries (*phoros*) the essential features responsible for a drug's (pharmac^{on}'s) biological activity." Updated by Peter Gund in 1977 to describe "a set of structural features in a molecule that is recognized at a receptor site and is responsible for that molecule's biological activity."

Urocortins

Structurally related mammalian paralogs of corticotropin-releasing factor (CRF). Though these three known peptides (urocortins (Ucn) 1, 2, and 3) share sequence identity with CRF, each CRF family peptide is coded by a different gene and has different pharmacological properties, tissue distributions, and regulatory pathways, leading to their diverse roles in stress responses to homeostatic threats. Urocortins, unlike CRF, exhibit high affinity for CRF₂ receptors.

Corticotropin-releasing factor (CRF) receptor antagonists have been sought since the isolation of the eponymous stress-related adrenocorticotropin-releasing peptide in 1981 by Vale and colleagues. Discovered for its hypophysiotropic function in the hypothalamic-pituitary-adrenal (HPA) axis, CRF and, later, urocortins (Ucn)-1, -2, and -3, paralogs of CRF, were subsequently found also to play roles in diverse homeostatic stress responses, via extra-hypothalamic brain sites and peripheral tissues. CRF receptor antagonists have potential therapeutic applications in cases where these responses are inappropriate in magnitude, timing, or context.

Pharmacology of Corticotropin-Releasing Factor/Urocortin Receptor Systems

CRF-related peptides interact with two known mammalian CRF receptor subtypes, CRF₁ and CRF₂, both belonging to the class B1 (secretinlike) subfamily of

G-protein-coupled receptors for polypeptide hormones. The CRF₁ receptor has been cloned in humans, mice, rats, and tree shrews, among other species, and exists in multiple isoforms (e.g., CRF_{1a}–CRF_{1h}), with the best known and functional isoform being the CRF_{1(a)} subtype. The CRF₂ receptor has three known functional membrane-associated subtypes in humans, CRF_{2(a)}, CRF_{2(b)}, and CRF_{2(c)}, as well as a ligand-sequestering, soluble CRF_{2(a)} isoform discovered in mice. CRF₂ and CRF₁ receptors have ~70% sequence identity. Whereas CRF has high, preferential affinity for CRF₁ versus CRF₂ receptors, Ucn 1 is a high-affinity agonist at both receptors. The type 2 Ucns, Ucn 2 and Ucn 3 are more selective for membrane CRF₂ receptors. Because of this pharmacological profile, references to antiCRF treatments most often refer to functional or competitive antagonists of CRF₁ receptor-mediated effects, whereas antitype 2 Ucn treatments might target CRF₂ receptors. The biological actions of CRF, Ucn-1, and Ucn-2 in rodents also are modulated by a CRF-binding protein (CRF-BP), a 37-kD secreted glycoprotein that binds and putatively immunosequesters CRF and Ucn-1 with equal or greater affinity than do CRF receptors. However, structural requirements for binding to CRF receptors and the CRF-BP differ, so many (if not most) CRF receptor antagonists do not interact with the CRF-BP.

Nonneuroendocrine Distribution of CRF₁ Receptors

CRF₁ receptors mediate not only the HPA-axis neuroendocrine response to stress, but also other aspects of organism stress responses. In brain, the distribution of CRF₁ receptors is highly conserved in stress-responsive brain regions, including neocortex,

the extended central amygdala, medial septum, hippocampus, hypothalamus, thalamus, cerebellum, and autonomic midbrain and hindbrain nuclei. This receptor distribution, concordant with that of its natural ligands (CRF, Ucn-1), is consistent with the proposed role for extrahypothalamic CRF₁ receptors in behavioral and autonomic stress responses. Accordingly, excessive CRF₁ signaling putatively has a pathophysiological role in several stress-related disorders, including anxiety and depressive disorders, substance dependence, and irritable bowel syndrome. Hereafter, the identity and potential therapeutic indications for CRF₁ receptor antagonists are summarized.

Selected Corticotropin-Releasing Factor Receptor Antagonists

Nonselective Peptide Corticotropin-Releasing Factor Receptor Antagonists

N-terminally truncated and substituted analogs of CRF can act as competitive partial agonists or full receptor antagonists (Table 1). Examples of these, in chronological order of discovery, include the partial agonist [Met¹⁸,Lys²³,Glu^{27,29,40},Ala^{32,41},Leu^{33,36,38}]r/hCRF₉₋₄₁ (also known as α -helical CRF₉₋₄₁); and the full receptor antagonists [D-Phe¹²,Nle^{21,38},C α MeLeu³⁷]r/hCRF₁₂₋₄₁ (also known as D-Phe-CRF₁₂₋₄₁); cyclo(30-33)[D-Phe¹²,Nle^{21,38},Glu³⁰,Lys³³]r/hCRF₁₂₋₄₁ (also known as astressin); and cyclo(30-33)[D-Phe¹²,Nle²¹,C α MeLeu²⁷,Glu³⁰,Lys³³,Nle³⁸,C α MeLeu⁴⁰]Ac-r/hCRF₉₋₄₁ (also known as astressin-B). These peptide ligands have roughly the same order of binding and antagonist potency at CRF₁ versus CRF₂ receptors and do not cross the blood–brain barrier. Thus, they are subtype nonselective, peripherally acting CRF receptor antagonists.

Table 1 Alphabetical selection of peptide CRF receptor antagonists

Familiar name	CRF receptor binding affinity (IC ₅₀ or K _i)		Chemical structure
	CRF ₁ (nM)	CRF ₂ (nM)	
α -helical CRF ₉₋₄₁	19	1.1	[Met ¹⁸ ,Lys ²³ ,Glu ^{27,29,40} ,Ala ^{32,41} ,Leu ^{33,36,38}]r/hCRF ₉₋₄₁
Antisauvagine-30	400	1.1	[D-Phe ¹¹ ,His ¹²]sauvagine ₁₁₋₄₀
Astressin	13.2	1.5	Cyclo(30-33)[D-Phe ¹² ,Nle ^{21,38} ,Glu ³⁰ ,Lys ³³]r/hCRF ₁₂₋₄₁
Astressin-B	High affinity	Moderate affinity	Cyclo(30-33)[D-Phe ¹² ,Nle ²¹ ,C α MeLeu ²⁷ ,Glu ³⁰ ,Lys ³³ ,Nle ³⁸ ,C α MeLeu ⁴⁰]acetyl-r/hCRF ₉₋₄₁
Astressin ₂ -B	>500	1.3	Cyclo(31-34)[D-Phe ¹¹ ,His ¹² ,C α MeLeu ^{13,39} ,Nle ¹⁷ ,Glu ³¹ ,Lys ³⁴]acetyl-sauvagine ₈₋₄₀

Subtype-Selective Peptide Corticotropin-Releasing Factor Receptor Antagonists

Antisauvagine-30 was reported as the first preferential CRF₂ antagonist. Following its development, several subsequent series of CRF₂ receptor peptide antagonists have been identified, each of which is more potent, selective, and enzymatic degradation resistant than antisauvagine-30. These new antagonists included the antisauvagine-30 analogs K31440 and K41498; [Tyr¹¹, His¹², Nle¹⁷]SVG₁₀₋₄₀, which has 2360-fold selectivity and subnanomolar affinity for the CRF₂ receptor; and astressin₂-B, a long-acting, potent, and selective CRF₂ antagonist (Table 1). Although these antagonists do not oppose the classic stress-related effects of CRF reviewed above, they do reverse stress-induced CRF₂-mediated endpoints, some of which are recruited by Ucn3 and some by CRF. Such endpoints include, for example, stress-induced gastric stasis and, possibly a component of stress-induced anorexia.

Selective CRF₁ peptide antagonists also appear to have been identified recently in the course of seeking minimal peptide fragments with CRF receptor antagonist activity. For example, Yamada and colleagues followed upon a patent application (W01/29086) of the Solvay pharmaceutical group which described a peptide comprising the 12 C-terminal residues of astressin as a potent antagonist of CRF receptors. Through amino acid substitution, of Nle38 with the bulkier, lipophilic cyclohexylalanine residue and of Ala31 with an unnatural residue (D-Ala), they identified a metabolically stable, high-affinity ($K_i \sim 3$ nM) CRF₁ antagonist that potently (0.1 mg kg⁻¹ intravenous; IV) reduced adrenocorticotrophic hormone (ACTH) secretion in a rat model of sepsis. This peptide is likely a selective CRF₁ antagonist because the Solvay group concurrently published their findings on the patented 12-residue N-terminal truncated astressin derivative on which Yamada and colleagues began their investigation. The disclosed fragment not only retained CRF₁ affinity, but was inactive at the CRF_{2(a)} receptor. Thus, it appears that lactam bridge-constrained N-terminally truncated astressin derivatives of 12–15 residue length may be selective CRF₁ receptor peptide antagonists. Such compounds could be useful for the treatment of pathologies that involve only peripheral CRF₁ hyperactivation.

Small-Molecule CRF₁ Receptor Antagonists

Pharmacophore and selectivity Small molecules that penetrate the blood–brain barrier with high and selective CRF₁ (versus CRF₂) affinity also have been identified (Table 2) and reviewed in considerable detail recently. With few exceptions, every known CRF₁

antagonist follows a common pharmacophore. Prototypical compounds (see Figure 1) share one or two lipophilic top/side units, a central mono-, bi- or tricyclic ring core, and a conformation-stabilizing di- or trisubstituted aromatic bottom group. Each ring core contains a putative proton-accepting ring nitrogen, and the hydrogen-bond accepting core is thought to interact with histidine-199 of the CRF₁ receptor, a polar amino acid in the third transmembrane domain that is not shared in the CRF₂ receptor or CRF-BP sequences. Therefore, CRF₁ antagonists with this pharmacophore are highly selective (CRF₁ versus CRF₂ and CRF-BP). Most known small-molecule CRF₁ receptor antagonists also show at least 1000-fold binding selectivity relative to other receptors, ion channels, and reuptake sites screened to date. However, this is not universal as one exception, R278995 (also known as CRA0450), actually exhibits 50-fold greater affinity for the σ_1 receptor than for the CRF₁ receptor.

The binding site of the classic pharmacophore also differs from the agonist binding site, whose confirmation is allosterically modified by CRF₁ antagonists, making these small molecules noncompetitive antagonists of peptide ligands. Exceptions to the pharmacophore include oxo-7H-benzo[e]perimidine-4-carboxylic acid derivatives, which are subtype nonselective CRF receptor antagonists discovered by Alanex; CC 2064460, a moderately potent arylamidrazone CRF₁ antagonist that lacks a central ring core with the customary hydrogen-bond accepting nitrogen; and stereospecific N-phenylphenylglycines, which also lack a ring core but were identified through computational screening based on a classic pharmacophore training set.

Lipophilicity An obstacle in the clinical use of CRF₁ antagonists is that most preclinical structures have been excessively lipophilic with poor water solubility, bioavailability, and pharmacokinetic properties. For example, the rank-ordered oral bioavailabilities of antalarmin (19%) < CP-154,526 (27%) < DMP904 (33%) < DMP696 (37–50%) follow the inverse rank of their cLogDs and cLogPs. Accordingly, the oral dose (30 mg kg⁻¹) of CP-154,526 needed to achieve the anxiolytic-like threshold of brain CRF₁ receptor occupancy in rats (~50–60% of receptors bound) is one order higher than that required by the similar affinity, but much less hydrophobic, compounds DMP696 (1–3 mg kg⁻¹), R121919 (2.5 mg kg⁻¹), and SSR125543A (6.5 mg kg⁻¹). Because of their high lipophilicity, many CRF₁ receptor antagonists have very high estimated bioconcentration factors at physiological pHs, a potential index of toxicity liability. Most early CRF₁ antagonists also failed Lipinski's

Table 2 Alphabetical selection of small-molecule CRF₁ receptor antagonists

^aAlso known as NBI-30775;^bAlso known as CRA0450;^cCAS, Chemical Abstract Service, a database of chemical substance information; ND, not determined.Table modified from Zorrilla et al., 2003 (with permission from Elsevier) and Zorrilla & Koob, 2004 (with permission from *Expert opinion on Investigational Drugs*).

“rule of 5” criteria for drug candidates, derived from a review of physiochemical properties of compounds within the United States Adopted Names database, due to excessive lipophilicity (cLogP > 5). Due to unfavorable pharmacokinetics, this degree of lipophilicity is rare for effective central nervous system (CNS)-acting agents. Of more than 100 drugs

marketed as of 1992 for CNS indications, not one had a logD greater than 4; most (~85%) had a logD of 0–3. Much preclinical discovery since 2002 has therefore focused on identifying less hydrophobic CRF₁ antagonists, with recent success. Early studies indicate that CRF₁ antagonists as a class do not share some of the drawbacks of benzodiazepines, such as

Figure 1 Representative selection of heterocyclic, small-molecule selective CRF₁ receptor antagonists that conform to the classic CRF₁ antagonist pharmacophore. See text for description of pharmacophore structural features and [Table 2](#) for chemical structure, CAS registry numbers, and binding properties of each compound.

tolerance, sedative-hypnotic, or amnesic effects, or abuse liability. They also do not lead to HPA-axis insufficiency at preclinically therapeutic doses, but isolated reports of liver enzyme elevations led to the discontinued clinical development of R121919, which had shown dose-related efficacy in an open-label Phase IIa clinical trial of patients with major depression.

Therapeutic Potential of CRF₁ Antagonists

Endocrine Disorders

CRF released into the portal blood from the median eminence stimulates ACTH release from the anterior pituitary into systemic circulation, which elicits the synthesis and release of glucocorticoids from the adrenal cortex – the classic HPA-axis stress response. HPA-axis dysregulation can result in endocrine disorders of hypercortisolemia, including Cushing's syndrome. Most cases of Cushing's syndrome are iatrogenic (e.g., from synthetic glucocorticoids), or due to ACTH- or cortisol-hypersecreting tumors and hyperplasias. However, central hypersecretion of neuroendocrine CRF leads to a Cushingoid state, exemplified in CRF-overexpressing transgenic mice. Likewise, clinical syndromes with hypothalamic CRF-driven chronic hypercortisolemia, including severe alcohol dependence, visceral obesity, melancholic major depression, and anorexia nervosa, are marked by Cushingoid somatic and endocrine features that remit when cortisol levels normalize. Peripherally acting, long-acting peptide CRF receptor antagonists, such as astressin-B, have been especially effective in opposing CRF-evoked ACTH release and therefore may have a therapeutic role in managing Cushingoid consequences of these disorders, if not also the disorders themselves.

Sympathoadrenomedullary Response

Intracerebroventricular (ICV) CRF administration evokes the sympathoadrenomedullary stress response in animal models, as it elevates blood pressure and heart rate; increases circulating levels of catecholamines, glucagon, and glucose; increases body temperature; and raises energy expenditure. Conversely, in animal models, CRF receptor antagonists, in particular those for the CRF₁ subtype such as CP-154,526, attenuate both CRF- and stress-induced tachycardia, hypertension, and hyperthermia.

Central Nervous System-Related Disorders

Anxiety disorders Consistent with autonomic findings, clinical data suggest that brain CRF is hypersecreted in some pathological anxiety conditions. Cerebrospinal (CSF) CRF levels, which mostly reflect nonneuroendocrine brain CRF secretion, are high in some patients with posttraumatic stress disorder, underweight patients with anorexia nervosa, ethanol withdrawn alcoholics, and some adults with obsessive-compulsive disorder, all conditions marked by high anxiety levels. Conversely, effective treatment of juveniles with obsessive-compulsive disorder with the tricyclic antidepressant clomipramine decreased their CSF CRF levels.

The anxiolytic-like actions of nonselective peptide and small-molecule CRF₁ receptor antagonists, CRF₁ knockout, and CRF₁ antisense knockdown all collectively emphasize an endogenous role for extrahypothalamic, limbic CRF₁ neurotransmission in hyperarousal and anxiety. For example, ICV α -helical CRF₉₋₄₁, a nonselective CRF receptor partial agonist, reversed the ability of restraint, foot shock, or social isolation to wake rodents prematurely from pentobarbital-induced sleep, and small-molecule CRF₁ antagonists like CRA1000 and R121919 also mitigate

insomnia-like effects of stress on sleep. Stress or CRF administration also increase locomotor activity in familiar environments, a sign of behavioral hyperarousal that is blocked by pretreatment with CRF₁ receptor antagonists and absent in CRF₁-deficient mice.

Nonselective or CRF₁ receptor antagonists also reduce the avoidance of unfamiliar, exposed areas in the open field, elevated plus maze, defensive withdrawal, or light/dark box tests by rodents that were stressed by restraint, swim stress, social defeat, conspecific stress, ethanol withdrawal, conditioned effects of psychostimulants, or novelty (but these actions are not observed in unstressed rodents). Knock-out of CRF₁, but not CRF₂, receptors in mice or antisense knockdown of CRF₁, but not CRF₂, receptors in rats likewise produces anxiolytic-like effects in exploration-based models of anxiety. Anxiolytic-like actions of nonselective or CRF₁ receptor antagonists are not limited to exploration-based models as they also were seen in rodent models of foot shock or conditioned freezing, fear- or light-potentiated acoustic startle, shock-induced defensive burying, social interaction, neonatal isolation-induced pup ultrasonic vocalization, and in unconditioned conflict models, such as punished drinking and punished crossing. Peptide nonselective or nonpeptide CRF₁ antagonists also reduced stress-induced anorexia in rats and unconditioned submissive/defensive behaviors in social defeat models. In nonhuman primates, CRF₁ exhibited oral anxiolytic-like action as well. For example, in rhesus monkeys, DMP904 (effective dose inducing 50% reduction (ED₅₀) 21 mg kg⁻¹) reduced stereotypical mouthing of rhesus monkeys in a human intruder test, and antalarmin (20 mg kg⁻¹) attenuated behavioral signs of anxiety, normalized exploratory, and sexual activity, and decreased HPA-axis and sympathoadrenomedullary hormone responses. Finally, depressed patients who participated in the open-label clinical trial with R121919 reported a reduction of anxious symptoms (and improved sleep quality) in relation to escalating doses of the small-molecule CRF₁ antagonist.

Anxiolytic-like efficacy of antagonists is evident once they occupy 50–60% of brain CRF₁ receptors in rats, with further efficacy seen with incremental brain receptor occupancy. Acute anxiolytic-like efficacy of CRF₁ antagonists does not depend on actions at the HPA axis, as at least six compounds (antalarmin, CP-154,526, CRA1000, CRA1001, DMP904, and R121919) reduced anxiety-like behavior at doses that did not reduce ACTH or corticosterone responses to stress. The importance of central as opposed to pituitary CRF₁ receptors in anxiety-like behavior is highlighted by the finding that

limbic-selective deletion of CRF₁ receptors in mice is sufficient to produce anxiolytic-like effects. Anxiogenic-like CRF signaling may be mediated by mitogen-activated protein (MAP) kinase extracellular signal-related kinase 1/2 (ERK1/2) pathways in the forebrain. Consistent with these findings and sites of anxiogenic-like action by exogenous CRF, the locus coeruleus, bed nucleus of the stria terminalis, and amygdala are sensitive to site-specific anxiolytic-like CRF₁ antagonist administration.

Depression Evidence for increased extrahypothalamic CRF activity, perhaps due to tonic, stimulatory glucocorticoid action on CRF synthesis, has also been observed in affective disorders and may contribute to depressive symptomatology. Patients with major depression exhibit signs of chronic hypothalamically driven HPA-axis hyperactivation, including hypercortisolemia, blunted ACTH responses to CRF infusion, nonsuppression in the dexamethasone suppression test, and increased numbers of paraventricular nucleus (PVN) CRF neurons postmortem. The resulting excess glucocorticoid levels exert positive feedback on extrahypothalamic CRF systems in the amygdala and bed nucleus of the stria terminalis, and thereby may lead to behavioral symptoms of depression. Accordingly, abnormally high CSF CRF levels are seen in severely depressed patients, who frequently exhibit comorbid pathological anxiety. Although CSF CRF concentrations are not elevated in patients with bipolar disorder, chronic administration of effective pharmacotherapies for bipolar disorder decreases amygdala CRF₁ receptor synthesis or expression in rats. Finally, very high CSF CRF levels and downregulated cortical CRF receptor binding and mRNA expression also were seen postmortem in patients who committed suicide.

Consistent with the therapeutic potential of CRF₁ antagonists for major depression, subchronic dosing with DMP696 or R121919 reduced mouse forced-swim immobility, and acute antalarmin reduced forced-swim immobility in CRF₂ knockout mice, a genetic model of high-stress responsiveness. Also, antalarmin, SSR125543A, or CRA1000 reduced forced-swim immobility in outbred rats, and chronic SSR125543A treatment increased swimming in Flinders Sensitive Line rats, a putative genetic model of depression. Findings are somewhat equivocal, however, as antalarmin, CP-154,526, DMP904, R121919, and DMP696 had no reliable effect on forced-swim immobility in normal mice, with negative findings seen after acute, subchronic, and even chronic (16 days) dosing, unlike positive antidepressant controls. Each of these antagonists, as well as R278995, also lacked activity in the tail suspension test with acute dosing.

CP-154,526, CRA1000, and R278995 also can reduce the acquisition of learned helplessness. However, despite an initial report with CP-154,526 that showed reversal of shuttlebox escape deficits, subsequent studies with CP-154,526, DMP904, DMP696, or CRA1000 have not found that CRF₁ antagonists could acutely reverse learned helplessness in rats, once established.

R278995 reduced hyperemotionality of olfactory bulbectomized rats, regarded by some as a depression model, though it lacked antidepressant-like activity in the rat differential-reinforcement-of-low-rate 72-sec model. Chronic antalarmin or SSR125543A treatment also improved physical coat appearance in a mouse model of chronic mild stress, a fluoxetine-like effect that correlated with reversal of stress-induced suppression of hippocampal neurogenesis. The chronicity of treatment may be relevant for antidepressant CRF₁ action as repeated administration of CRF₁ antagonists has somewhat more often resulted in antidepressant-like activity. Consistent with this perspective, depressed patients treated with escalating doses of R121919 in an open-label study reported reduced depressive symptoms and showed normalization of sleep electroencephalography. Clinically, CRF₁ gene haplotypes also predict differential treatment response to fluoxetine in anxious, depressed Mexican-American people.

As was observed for anxiolytic-like activity, antidepressant-like activity appears to be dissociable from acute actions on HPA-axis activity, supporting the role of extrahypothalamic CRF in proximately mediating depressive-like symptoms. For example, acute R121919, CP-154,526, and R278995 failed to reduce rat forced-swim immobility, despite the fact that R121919 could reduce concurrent swim-induced ACTH secretion. Conversely, LWH234 (a different CRF₁ antagonist) did reduce forced-swim immobility, but at a dose which had no effect on swim-induced ACTH secretion.

Gastrointestinal Disorders

CRF₁-receptor antagonists also might be promising tools for the treatment of functional gastrointestinal disorders, including irritable bowel syndrome. In animal models, diverse stressors delay gastric emptying and stimulate colonic motor function, and endogenous CRF, through both brain and peripheral receptors, mediates these stress-induced changes in gastrocolonic motility. The colonic-stimulating effects of stress are observed as colonic hypermotility, decreased transit time, defecation, and watery diarrhea and are mimicked by ICV administration of CRF or Ucn-1 in rats, mice, and Mongolian gerbils.

Central or peripheral administration of selective CRF₁, but not CRF₂, agonists stimulates colonic motility, and selective CRF₁, but not CRF₂, antagonists attenuate stress- or CRF/Ucn-1-induced stimulation of colonic motor function. For example, selective CRF₁ receptor antagonists such as CP154,526, CRA1000, NBI-35965, NBI-27914, and antalarmin, injected peripherally or ICV, blunted the acceleration of colonic transit induced by restraint; the defecation induced by water avoidance stress, restraint, or social stress; and the diarrhea induced by morphine withdrawal. Likely substrates for CRF₁-mediated stimulation of colonic motor function include, centrally, the PVN and locus coeruleus/Barrington nuclei that activate sacral parasympathetic nervous system activity, and, peripherally, the colonic myenteric nervous system.

CRF₁ receptor signaling is also involved in visceral hyperalgesia. For example, both stress and ICV CRF induce visceral hyperalgesia to colorectal distention in rats, and these actions of stress can be blocked by ICV α -helical CRF₉₋₄₁. More recently, systemic administration of NBI-35965, a nonpeptide CRF₁ antagonist, was found to block water avoidance stress-induced hyperalgesia to colorectal distention in adult offspring of maternal separation. Antalarmin (by intraperitoneal (IP) route) likewise reduced ICV CRF-induced hypersensitivity to colorectal distention and also blunted the visceral hyperalgesia of high-anxiety strain rats. Finally, α -helical CRF₉₋₄₁ attenuated electrical stimulation-induced visceral symptoms in patients with diarrhea-predominant irritable bowel syndrome.

CRF₁ receptors are involved in the early phase of postoperative gastric ileus. Peripheral CP-154,526 administration prevented abdominal surgery-induced slowing of gastric emptying. Similarly, CRF₁ knockout mice did not show postoperative gastric ileus, whereas abdominal surgery inhibited postoperative gastric emptying by 75% in wild-type mice.

CRF₂ receptor antagonists might be effective treatments to relieve stress-induced gastric stasis and perhaps other adverse gastroparesis. Stress or central infusion of CRF receptor agonists, through vagal effectors, delay gastric emptying, reduce antral gastric motility, inhibit high-amplitude gastric contractions, and shift duodenal activity from fasted to fed motor patterns, actions reversed by central astressin₂-B (CRF₂), but not NBI-27914 treatment. Complementing the central CRF₂ pathway for slowing gastric emptying, peripheral (by IV or IP route) injection of high-affinity and/or selective CRF₂ agonists (Ucn-1, Ucn-2, or Ucn-3) also delays gastric emptying more potently than CRF. Conversely, systemic pretreatment with CRF₂ (e.g., antisauvagine-30 or

astressin₂-B), but not CRF₁ (e.g., CP-154,526, DMP904, and NBI-27914) antagonists blocks the gastromotor inhibiting effects of Ucn₁ as well as restraint stress-induced gastric stasis. Thus, stress releases CRF like peptides that inhibit gastric motility through the brain–gastrointestinal tract CRF₂ receptor systems. Likely substrates include the PVN and dorsal vagal complex in the brain, and myenteric fibers of the enteric nervous system in the periphery.

Urologic Disorders

Epidemiologic and clinical findings indicate comorbidity of anxiety with several urologic problems, including overactive bladder, interstitial cystitis, and incontinence. In feline models of interstitial cystitis, CSF CRF levels are increased and subjects show exaggerated acoustic startle reactivity. This is somewhat expected because of the overlap in neuroanatomical substrates of CRF-related emotional responding and of micturition and pelvic viscerosensation. Shared neural substrates include Barrington's nucleus, amygdala, hippocampus, and prefrontal cortex. CRF also appears to play a role in the control of micturition and bladder sensation via the spinal cord. In particular, CRF immunoreactivity is present in intermediolateral cell column, suggesting a role in urinary motor function, and in sensory processing areas, including the dorsal horn, medial and lateral collateral pathways, dorsal intermediate gray, and laminae VII and X. Early studies indicate that CRF dose-dependently promotes micturition in awake animals, whereas CRF receptor antagonists have an inhibitory effect. Furthermore, CRF receptor antagonists have reversed bladder overactivity in animal models.

Pregnancy and Parturition

Changes in circulating CRF, Ucn-1, and CRF-BP levels help coordinate the events of pregnancy and parturition. CRF is produced in the hypothalamus and placenta during pregnancy, and placental CRF accesses both maternal and fetal circulations. During pregnancy, placental CRF secretion increases exponentially, peaking at birth. Accordingly, maternal plasma CRF levels increase from the second trimester exponentially towards term, rise dramatically during labor, and fall quickly after birth. Unbound (free) CRF levels are regulated by CRF-BP levels, which normally decrease near term (36 weeks' gestation), resulting in a dramatic increase in bioavailable maternal plasma CRF. Women with preterm labor show high CRF and low CRF-BP levels, suggesting an involvement of high bioavailability of maternal CRF in the onset of parturition. Consistent with this perspective, maternal free CRF measurement predicts outcome of

certain at-risk pregnancies, and the regulation of the length of gestation by CRF has been termed a placental clock. For example, the highest levels of maternal CRF at 20 weeks' gestation are observed in high-risk populations that ultimately deliver before 34 weeks. A prospective study of 232 pregnancies likewise observed that elevated maternal plasma CRF levels at 33 weeks' gestation carried a 3.3-fold greater risk of preterm birth, whereas women who delivered postterm had lower circulating CRF levels at that time than mothers who delivered at term. Similarly, a prospective study of 282 pregnancies found that maternal plasma CRF levels at 18–20 weeks and 28–30 weeks' gestation were higher in women who ultimately delivered preterm. Thus, CRF₁ antagonists might delay premature birth. Supporting this hypothesis, CRF₁ receptor antagonists delayed the onset of labor in sheep model studies.

Inflammatory States

CRF is a proinflammatory peptide via direct autocrine/paracrine actions in immune and immune lineage cells. In brain, CRF and/or its receptors are localized in microglia, astrocytes, and infiltrating monocytes/macrophages. In the periphery, CRF receptors are found in macrophages, lymphocytes, and mast cells. Immune CRF and Ucn-1 are expressed by human cord blood-derived cultured mast cells by the 10th gestational week and also are produced by human leukemic mast cell lines. In addition to mast cells, Ucn-1 also is seen in lymphocytes, macrophages, and fibroblasts, a cellular distribution that underlies moderate overall expression in thymus, spleen, and skin.

Supporting proinflammatory properties for CRF and Ucn-1, both peptides provoke resting monocytes to secrete interleukin (IL)-1 β and IL-6 *in vitro* via a CRF₁-mediated mechanism, and CRF triggers lymphocyte proliferation. CRF activates microglia, stimulates astrocytosis and monocyte migration, and augments macrophage production of free radicals and arachidonic acid. CRF receptor ligands also activate mast cells *in vitro*, an action that can be blocked by the CRF₁ antagonist antalarmin, but not the CRF₂ antagonist astressin₂-B and which leads to release of vascular endothelial growth factor, which is elevated in arthritis, psoriasis, and other chronic inflammatory conditions. The findings suggest a potential anti-inflammatory role for CRF₁ antagonists.

Inflammatory disorders Correspondingly, CRF immunoreactivity is elevated in local immune accessory cells in experimental models of arthritis and uveitis, and increased CRF or Ucn-1 immunoreactivity also are evident in human inflamed tissue, including

joints of patients with rheumatoid arthritis, lamina propria macrophages of patients with ulcerative colitis, reproductive tissue of patients with endometriosis, and thyroid glands of patients with Hashimoto's thyroiditis. The number of Ucn-1-positive cells in synovia of arthritic patients correlates strongly with inflammation severity. Conversely, chronic systemic antalarmin treatment reduced joint inflammation in an adjuvant-induced arthritis model in LEW/N rats. Also, CRF₁ agonists (IP) increase intestinal mucosal permeability to macromolecules, and chronic psychosocial stress reduces intestinal host defense and initiates intestinal inflammation through a mast cell CRF₁ receptor-dependent mechanism.

Neurological insults Excitotoxic, ischemic, and hypoxic brain insults upregulate CRF production in topographic and temporal relation to neuronal injury, and CRF potentiates ischemia-induced neuronal apoptosis in the presence of microglia *in vitro*. Conversely, CRF receptor antagonists reduced neuronal death induced by diverse brain injuries independent of the adrenocortical axis. R121920, a small-molecule CRF₁ antagonist, reduced infarct volume at 24 h in subtemporal and intraluminal suture middle cerebral artery occlusion models even when treatment was delayed up to 1 h postocclusion. Astressin, a nonselective peptide CRF antagonist also ameliorated the effects of 15-min ischemia in a Schaffer collateral-CA1 field potential hippocampal slice model. Central astressin treatment, prior to, or following, infantile seizures also decreased damage in hippocampal cell fields by 84%, perhaps also reflecting the antiexcitotoxic and not only anti-inflammatory properties of CRF₁ receptor antagonists.

Atopic/allergic disorders Stress worsens cutaneous diseases, such as psoriasis and atopic dermatitis. Recent evidence suggests that CRF/Ucn-1 crosstalk between mast cells, neurons, and keratinocytes underlie such exacerbation. Skin mast cells, which play a role in allergy and inflammation by releasing histamine, proteases, proteoglycans, prostaglandin D₂, and leukotriene C₄, secrete CRF and Ucn-1 in response to psychosocial stress. Accordingly, acute psychosocial stress increases skin CRF levels and triggers mast cell-dependent vascular permeability, which also results from intradermal CRF application. CRA1000, a CRF₁ antagonist, blocks the actions of repeated stress to thicken the epidermis and increases mast cell numbers in dermis, suggesting a role for CRF₁ receptors in chronic contact dermatitis. Mast cells also release CRF and Ucn-1 in response to immunoglobulin E

receptor cross-linking, suggesting a general role for CRF₁ activity in atopic disorders.

Glucocorticoid Receptors

Neuroendocrine Abnormalities in Depressive Disorders

Antidepressant Action

How Antidepressants May Regulate GR

Glossary

<i>Atypical antidepressants</i>	Include compounds that act similarly to tricyclic antidepressants but have a different chemical structure; also compounds with different pharmacological actions.
<i>Dexamethasone suppression test</i>	A clinical test to check the sensitivity of the hypothalamic-pituitary-adrenal stress axis. The synthetic steroid dexamethasone is injected and the fall in plasma cortisol levels is measured. Patients with major depression fail to respond with the normal fall in plasma cortisol seen in control subjects.
<i>Glucocorticoid receptors</i>	~94 kDa intracellular protein that mediates the effects of glucocorticoid hormones. They are also known as ligand-activated transcription factors since in the hormone-bound state, these receptors specifically bind to and modulate the activity of target gene promoters.
<i>Glucocorticoids</i>	A major subclass of steroid hormones produced by the zona fasciculata cells of the adrenal cortex that regulate fuel metabolism and mediate part of the stress response as well as aspects of immunosuppression and inflammation and behavioral functions.
<i>Monoamine oxidase inhibitor</i>	Type of antidepressant drug that inhibits one or both forms of brain monoamine oxidase (MAO), thus increasing the cytosolic stores of norepinephrine, dopamine, and 5-HT in nerve terminals.
<i>Multidrug resistance P-glycoprotein (PGP)</i>	A steroid transporter localized on the blood–brain barrier that limits the access of dexamethasone and cortisol to both mouse and human brain.

Transcription factors

Regulatory agents that are not part of the regulated gene(s). These *trans*-acting factors regulate gene transcription by binding directly or through an intermediate protein to the gene at a particular DNA sequence, called a *cis*-regulatory region, usually located in the 5' flanking promoter region of the gene.

Tricyclic antidepressants

Drugs that act by inhibiting uptake of norepinephrine and/or 5-HT by monoaminergic nerve terminals, thus acutely facilitating transmission.

Following the termination of the stress response, negative feedback exerted by circulating glucocorticoids (GCs; corticosterone in rats and mice, cortisol in humans and most other mammals) via glucocorticoid receptors (GRs) acts upon the hypothalamic-pituitary-adrenal (HPA) axis to restore low basal GC levels. In patients with major depression, the HPA axis is hyperactive as indicated by elevated circulating cortisol levels. This has led to the hypothesis that GR expression and/or function in depression may be abnormal. Successful therapy with antidepressant drugs restores HPA axis feedback sensitivity and lowers basal cortisol levels. One important aspect of antidepressant action may be to facilitate GR-mediated feedback inhibition upon the HPA axis by its actions on GR.

Glucocorticoid Receptors

The glucocorticoid receptor (GR) is a ligand-activated transcription factor that resides primarily in the cytoplasm as part of a multiprotein complex with heat shock proteins (hsps). This complex maintains unbound GRs in a ligand-accessible but inactive protein conformation. GCs are lipophilic substances and readily cross the cell membrane to interact with the intracellular GR. When activated by the binding of glucocorticoids (cortisol, corticosterone), the GR undergoes a conformational change, dissociates from the hsp complex, and translocates to the nucleus, where it binds to specific DNA sequences termed glucocorticoid-responsive elements (GRE) in the promoter region of glucocorticoid-responsive genes to influence gene transcription ([Figure 1](#)).

The hormone-activated GR can also act by interacting with other transcription factors in the absence of specific DNA binding. For example, GR inhibits

Figure 1 Simplified model of activation of glucocorticoid receptors. Glucocorticoids diffuse across the plasma membrane and bind to the glucocorticoid receptor (GR). Hormone binding causes a conformational change that causes dissociation of the GR–heat shock protein (hsp) complex and nuclear translocation. The activated GR binds as a homo- or heterodimer to glucocorticoid response element sequences (GREs) in the regulatory region of target genes to regulate transcription.

activating protein-1 (AP-1), a transcription factor composed of dimers of Jun and Fos family proteins, and thus represses transcription of AP-1-regulated genes such as collagenase and interleukin-2. Interaction with other transcription factors, such as cAMP response element binding protein (CREB), enhances GR-mediated transcription.

Glucocorticoid Feedback Regulation

Two types of adrenal steroid receptor have been described in the brain, a type 1 receptor indistinguishable from the peripheral mineralocorticoid receptor (MR) and a type 2 receptor indistinguishable from the peripheral GR. MR has a more restricted localization in brain and is most densely localized in hippocampal and septal neurons. GR, in contrast, is more diffusely distributed and is found particularly in areas within the limbic brain, not only in neurons but also in glia and vascular tissues. The hippocampus plays an important role in learning and memory and is also involved in HPA axis control. Much evidence supports an inhibitory role of the hippocampus, which thus suppresses HPA function. For example, lesions to the hippocampus usually lead to hypersecretion of GCs from the adrenals. MR and GR are particularly highly expressed in the hippocampus as shown using

molecular (e.g., *in situ* hybridization; see Figure 2), ligand binding, and immunohistochemical approaches. These two types of receptors bind GCs with differing affinities and act in coordination to regulate HPA axis function, with high-affinity MR controlling basal HPA activity during the nadir of the circadian rhythm of GC secretion, while lower affinity GRs are involved in the termination of the stress response.

Hippocampal MR and GR Density and HPA Activity

Manipulations that increase hippocampal GR, such as neonatal handling, a subtle environmental stress in which rat pups are physically removed from their mothers for 15 min daily during the first 2 weeks of life and which models some of the effects of naturally occurring variations in maternal care, improves sensitivity to GC negative feedback inhibition. In contrast, manipulations that decrease hippocampal GR density without neuronal damage, such as prolonged postnatal maternal separation or prenatal maternal stress or glucocorticoid exposure, reduce GC feedback sensitivity and therefore lead to chronic exposure to elevated GCs. Thus, the density of GR in the hippocampus is of crucial importance to feedback regulation of circulating GC levels. Hippocampal MRs are also important in terms of control of inhibitory

Figure 2 *In situ* hybridization localization of type 1 (mineralocorticoid receptor, top) and type 2 (glucocorticoid receptor, bottom) mRNA expression in the rat brain at the level of the dorsal hippocampus. Autoradiographs show MR expression is almost restricted to the hippocampus, while GR is more widespread but also highly expressed in the hippocampus.

tone over the HPA axis. Rat strains with high levels of hippocampal MR expression, such as the Lewis rat, show lower basal and stress-induced HPA activity compared with Wistar rats from which they are derived. Conversely, aged rats that generally have reduced hippocampal MR (and GR) expression show increased basal HPA activity. Central administration of endotoxin to rats, which impairs MR function, causes chronically elevated basal HPA activity.

Neuroendocrine Abnormalities in Depressive Disorders

Hyperactivity of the HPA axis is frequently found in patients with major depression who show increased concentrations of cortisol in plasma, urine, and cerebrospinal fluid and abnormal 24 h secretory patterns. These patients also fail to respond with the normal fall of plasma cortisol levels following administration of dexamethasone, a synthetic glucocorticoid that binds to GR. This forms the basis of the dexamethasone suppression test, one of the most widely studied

Figure 3 Schematic diagram of feedback control of HPA axis in depression. Cortisol suppresses the axis by binding to GRs in key feedback sites, hippocampus, paraventricular nucleus (PVN) of the hypothalamus, and pituitary gland. In major depression there is a hyperactive HPA axis with excess CRH and cortisol secretion, likely due to a hippocampal-hypothalamic defect.

endocrine tests in the history of psychiatry. A significant percentage (20–50%) of patients with major (melancholic) depression fail to suppress cortisol in response to dexamethasone challenge. This indicates inadequate GC feedback, which could be at any of a number of levels of the HPA axis (Figure 3).

In response to an intravenous dose of corticotrophin releasing hormone (CRH), patients with major depression secrete decreased amounts of ACTH. One possible mechanism to explain the blunted responsiveness to CRH could be pituitary hyporesponsiveness to CRH, itself due to CRH receptor desensitization (a consequence of sustained exposure to high CRH concentrations). Alternatively, another ACTH secretagogue may be implicated in HPA activation in depression (such as vasopressin). Finally, increased cortisol in patients with depressive illnesses may be inhibiting ACTH, but perhaps inadequately for the degree of elevation of plasma cortisol. To test this, a combination of dexamethasone suppression and then CRH stimulation (the dexamethasone/CRH test) has been used in patients with depression. Dexamethasone-pretreated patients show enhanced ACTH and cortisol responses to CRH, in contrast to earlier observations. These findings suggest that in severe depression, hypercortisolemia *per se* attenuates the ACTH response to CRH and that the equivalent basal state of the HPA axis is in fact

activated. The sensitivity (i.e., likelihood to differentiate normal from pathological state) of this DEX/CRH test is approximately 80%, which exceeds that of the standard dexamethasone suppression test. Thus, a limbic-hypothalamic defect resulting in excessive CRH output could explain the increased cortisol secretion in depression (Figure 3). This concept is supported by studies showing increased CRH levels in cerebrospinal fluid, increased postmortem hypothalamic CRH peptide and mRNA, and a lower than normal number of central CRH receptors among depressed patients.

Since GCs bind to MR and GR in brain sites involved in feedback control of HPA axis activity (i.e., MR and GR in the hippocampus, GR [and low levels of MR] in parvocellular neurons of the hypothalamus, anterior pituitary, and other sites), it has been suggested that depression may be associated with a primary imbalance of MR/GR expression and/or function. Although there is no direct evidence for reduced receptor concentrations in the brains of patients with depression, decreased GR mRNA expression have been reported in postmortem brain tissue (hippocampus and cortex) from individuals with major depressive disorder.

Antidepressant Action

Antidepressant drugs have been in use since the 1950s. Although clinically effective, their mechanism of action is still not clearly understood. Before 1980, the major classes of antidepressants in use were the tricyclics, monoamine oxidase inhibitors, and lithium. By the late 1980s, the serotonin reuptake inhibitors, currently the most commonly prescribed antidepressants, were introduced. All classes of antidepressants increase the concentration of biogenic amines (norepinephrine [NE] and/or serotonin [5-HT]) in the synaptic cleft. The ability of antidepressant drugs to facilitate monoaminergic transmission led to the monoamine theory, proposed in 1965, which suggests that depression results from functionally deficient monoaminergic transmission in the CNS. However, studies have not consistently shown a lack of biogenic amines or their metabolites in body fluids of depressed patients. There is also a clear discrepancy between the rapid effect of antidepressants in increasing synaptic concentrations of biogenic amines and the time course for the clinical efficacy of antidepressant treatment, which takes 2–3 weeks. A common, intracellular adaptation beyond the levels of 5-HT and NE and their receptors could account for the actions of the different types of antidepressants. Successful antidepressant treatment leads to normalization of HPA axis hyperactivity. Therefore, one such mechanism of antidepressant action is thought to be through direct

modulation of GR and/or MR in tissues involved in HPA feedback regulation.

Effects on HPA Function in Humans

Longitudinal studies in which depressed patients who were nonsuppressors of dexamethasone were retested weekly suggested that a return to dexamethasone suppressibility of plasma cortisol levels precedes the resolution of depressive psychopathology. Moreover, antidepressants may sometimes reduce CRH levels in human spinal fluid, suggesting that long-term administration of antidepressants may suppress the HPA system and that lowering HPA activity and clinical response are causally related. Finally, antidepressant resistant depression can be improved with GR synthesis inhibitors such as metyrapone.

Effects on HPA Function and Hippocampal Corticosteroid Receptors in Rats

Numerous studies in rats have shown that long-term *in vivo* treatment with a range of tricyclic and non-tricyclic antidepressants can enhance GC feedback inhibition (as indicated by decreased basal and/or stress-induced GC secretion) and/or increase corticosteroid receptor expression, particularly MRs, in the hippocampus (Table 1). An increase in MR and/or GR mRNA or binding in rat hippocampus can be observed irrespective of preferential inhibitory action of the antidepressant on reuptake of monoamines. This effect is dependent on the duration of antidepressant administration and requires weeks rather than days of treatment. For example, administration of the tricyclic antidepressant amitriptyline or moclobemide, a reversible inhibitor of monoamine oxidase type A (MAO-A), increased levels of hippocampal MR transiently by 40–70% between 2 and 5 weeks after the start of treatment. This is comparable to the increases in MR mRNA after long-term treatment with antidepressants. The levels of hypothalamic and hippocampal GR were also significantly increased by 20–25% at 5 weeks of treatment. The antidepressant-induced increases in brain GRs may underlie the observed decrease in basal circulating ACTH and corticosterone levels and in some cases decreased adrenal size. Indeed, the time course of antidepressant actions on GRs in the animal studies coincides with their long-term actions on HPA activity and follows closely that of clinical improvement of depression in humans. It is interesting to note that the antidepressant-induced increases in hippocampal MR are more pronounced than in GR and that the increases in the receptors are not maintained despite continual antidepressant treatment (Table 1). Systemic administration of antimineralocorticoids has been found to

Table 1 Antidepressant drug effects on mineralocorticoid and glucocorticoid receptor mRNA expression and binding sites in rat hippocampus

Antidepressant class	Drug	Dose/route	Duration	Hippocampal		Reference
				MR	GR	
Tricyclic	Amitriptyline (NE = 5-HT uptake)	20 mg/kg/day i.p.	2 weeks	87% incr (mRNA)	56% incr (mRNA)	Seckl, J. R. and Fink, G. (1992)
		10 mg/kg/day i.p.	10 weeks	17–28% incr (mRNA)	No effect	
		10 mg/kg/twice s.c. daily	3 weeks	16–29% incr (mRNA)	24–29% incr (mRNA)	Johansson, I. M. et al. (1998)
		4.5 mg/kg/day, p.o.	2–5 weeks	40–74% incr (binding sites)	0–26% incr (binding sites)	Reul, J. M. H. M. et al. (1993)
	Imipramine (NE > 5-HT uptake)	5 mg/kg/day i.p.	7 weeks	18% incr (binding sites)	No effect	Reul, J. M. H. M. et al. (1993)
			2–8 weeks	0–70% incr (mRNA)	No effect	Brady, L. S. et al. (1991)
	Desipramine (NE uptake)	10 mg/kg/day i.p.	2 weeks	60% incr (mRNA)	42% incr (mRNA)	Seckl, J. R. and Fink, G. (1992)
		10 mg/kg/day p.o.	4 weeks	32–36% incr (mRNA)	No effect	
MAO inhibitor	Moclobemide	4.5 mg/kg/day p.o.	2–5 weeks	65–76% incr (binding sites)	0–10% incr (binding sites)	Reul, J. M. H. M. et al. (1994)
			7 weeks	19% incr (binding sites)	No effect	Reul, J. M. H. M. et al. (1994)
Atypical Citalopram	(5-HT uptake)	20 mg/kg/day	2 weeks	17% incr (mRNA)	No effect	Seckl, J. R. and Fink, G. (1992)
	Fluoxetine (5-HT uptake)	5 mg/kg/day i.p.	2–8 weeks	0–56% incr (mRNA)	No effect	Brady, L. S. et al. (1992)
	Venlafaxine (5-HT > NE uptake)	10 mg/kg/day, p.o.	4 weeks	25% incr (mRNA)	No effect	Yau, J. L. W. and Seckl, J. R. (unpublished)

Abbreviations: i.p., interperitoneal; s.c., subcutaneous; p.o., oral route; incr, increase.

Note: The relative potency of antidepressant drugs in blocking reuptake of norepinephrine (NE) and serotonin (5-HT) shown in brackets. Full reference details in further reading.

impair the therapeutic efficacy of antidepressants, consistent with an important role for MRs in vulnerability to depression. MR controls basal HPA activity and, although not directly involved in the termination of the stress response, may influence the effects of GR on feedback control of the HPA axis. It is unclear how the lower plasma corticosterone levels are maintained long after hippocampal GR expression has returned to control levels and is no longer increased following long-term antidepressant treatment.

Effects in Transgenic Mice with Reduced GR Levels

To investigate the role of GR in HPA axis regulation and depression, several groups have generated mice with targeted GR deficiencies. Transgenic mice with impaired GR function were first created by attenuating mRNA expression with a GR antisense transgene leading to a 50% decrease in GR protein. These animals have numerous characteristics of human depression, including resistance to suppression of GCs by dexamethasone, feeding disturbances, and cognitive deficits. Long-term treatment with the antidepressant desipramine increased hypothalamic GR mRNA and binding, reduced HPA axis activity as shown by the partial reversal of enhanced ACTH and corticosterone secretion, and improved cognitive function. To dissect the role of brain GR from peripheral GR signaling and to rule out developmental effects, transgenic mice have recently been created with GR specifically disrupted throughout the hippocampus and most of the cortex in a time-dependent manner (GR immunoreactivity is lost in 60% hippocampal neurons at 2 months but not before 3 weeks of age and completely deleted by 6 months). These mice develop depression-like changes in adrenal axis regulation and behavior that mimic major depressive disorder in humans, including hyperactivity of the HPA axis (increased nadir and peak corticosterone release), impaired negative feedback inhibition of the HPA axis, and increased depression-like behavior (forced swim and tail suspension tests). Importantly, chronic treatment with the antidepressant imipramine reversed both the HPA axis abnormalities and behavioral phenotype despite the loss of GR action in these mice. This suggests that imipramine's known effects on forebrain GR are not crucial for its antidepressant effects and that the increase in MR mRNA expression in the hippocampus following imipramine may have compensated for the GR deficiency. These data support the hypothesis that a dysfunctional GR system may play a causative role in the etiology of depression.

Behavioral Effects of Antidepressant Actions via GR

There is now increasing evidence to link elevated cortisol levels in a subgroup of elderly humans to impaired memory associated with the hippocampus. Depression shows neuroendocrine abnormalities similar to those of unsuccessful aging, such as elevated GCs and impaired memory (dexamethasone nonsuppressors show significantly more commission errors in a word-learning paradigm [declarative memory] compared to suppressors). Chronically elevated GCs increase the vulnerability of the hippocampus to other insults, which may lead to structural and even neurotoxic tissue damage. Recent magnetic resonance image (MRI) studies have shown smaller hippocampal volumes in recurrent major depression and in healthy elderly subjects in whom cortisol levels are rising with age. Successful antidepressant drug therapy in major depression reverses hippocampal atrophy and cognitive impairments. Long-term treatment of middle-aged rats with the antidepressants amitriptyline or desipramine until 2 years old reduced the occurrence of hippocampal-dependent spatial memory impairments, and this may, in part, be a consequence of the reduced GC levels. Whether antidepressants can have the same effect in elderly humans with elevated cortisol levels and cognitive impairments has yet to be studied.

How Antidepressants May Regulate GR

Recent studies have focused on possible underlying mechanisms whereby antidepressant actions can modulate hippocampal GR. There is evidence to suggest that antidepressant effects, perhaps by increasing monoamines in the synaptic cleft, in particular 5-HT, start the cascade of events leading to increased transcription of GR. Serotonin acting via a ketanserin-sensitive cell surface receptor leads to increased second messenger (e.g., cAMP) levels in the cytosol of the cell, which in turn increases tertiary messengers, cAMP-dependent transcription factors in the nucleus, which might bind to the promoter of the GR gene to increase transcription ([Figure 4](#)).

Serotonin

5-HT increases GR mRNA and binding sites directly in hippocampal neurons in culture. This effect involves the second messenger cAMP and is blocked by ketanserin (mostly a 5-HT₂ receptor antagonist). Thus, 5-HT may act via a ketanserin-sensitive cell surface 5-HT receptor to increase GR. Antidepressant drugs may therefore increase hippocampal GR expression *in vivo* via its actions on potentiating monoaminergic (e.g., 5-HT and NE) neurotransmission.

Figure 4 Model of the action of chronic antidepressant treatments on GR. Antidepressants increase monoamines (5-HT or NE) in the synaptic cleft (1), which activate cell surface monoamine receptors coupled to the cAMP-protein kinase A cascade (2). This leads to increases in the second messengers cAMP and protein kinase A (3), leading to an increase in cAMP-dependent transcription factors in the nucleus (4), which may bind to the GR gene promoter to increase transcription. Alternatively, antidepressants may act directly to increase GR activity/DNA binding, possibly by inhibiting the membrane steroid transporter and thus inducing GR translocation from the cytoplasm to the nucleus (5).

Transcription Factors

Chronic antidepressant administration increases the expression of the nuclear transcription factor CREB in the rat hippocampus. Interestingly, temporal cortex CREB concentrations in major depressive disorder patients treated with antidepressants at the

time of death were higher than in untreated patients. CREB could be activated by 5-HT and NE receptors that directly stimulate cAMP production (e.g., 5-HT_{4,6,7} or β -adrenergic receptors) or 5-HT or NE receptors (e.g., 5-HT_{2A,C} and α 1-adrenergic receptors) that lead to stimulation of Ca^{2+} -dependent

protein kinases. Upregulation of CREB appears to be a common action of chronic antidepressant treatments, and since CREB can upregulate GR gene transcription, this may be one aspect whereby antidepressants facilitate GR-mediated feedback inhibition and thereby reverse GC hypersecretion in depression. Chronic amitriptyline treatment in rats has also been shown to increase the expression of another transcription factor, NGFIA, in the hippocampus. This transcription factor may bind to the GR promoter to increase transcription of GR.

Direct Modulation of GR

Treatment of primary cultures of rat brain hypothalamic neurons and hippocampal neurons for up to 14 days with the tricyclic antidepressants desipramine and amitriptyline increases GR mRNA (also GR binding sites and immunopositive cells) despite the lack of monoaminergic terminals in these cultures. A direct effect of antidepressants on GR was also shown when mouse fibroblast LTK cells or Neuro-2A treated with desipramine produced a 50–200% increase in the reporter gene chloramphenicol acetyltransferase (CAT) activity transcribed from a GR gene promoter region. These fibroblast cells do not secrete catecholamines, and therefore the desipramine-induced increase in GR gene activity involves a mechanism independent of NE reuptake inhibition.

Intriguingly, desipramine treatment for 24 h in mouse L929 fibroblast cells induced GR to translocate from the cytoplasm to the nucleus (using GR immunostaining technique) in the absence of exogenous steroid. Desipramine also potentiates dexamethasone-induced GR translocation and dexamethasone-induced GR-mediated gene transcription. One possible explanation for this steroid-independent modulation of GR *in vitro* could be that desipramine directly acts on one or more hsp and facilitates the dissociation of the receptor from the hsp complex.

Membrane Steroid Transporter

Membrane steroid transporters such as the multidrug resistance P-glycoprotein (MDR PGP) can regulate the function of GR and MR by modulating the intracellular access of steroid hormones. The MDR PGP, found in the endothelial cells of the blood–brain barrier, limits the access of dexamethasone and cortisol to both mouse and human brain. Antidepressants may modulate GR by inhibiting steroid transporters, thus increasing intracellular levels of steroids resulting in translocation of GR. MDR PGP inhibitors have been shown to induce partial GR translocation in HeLa (human ovarian cancer) cells, thus providing some evidence for this possibility. Translocation of GR could lead to the reduction in GR expression

(mRNA and binding sites) seen during the early phase of antidepressant actions (shown both *in vitro* and *in vivo* in rat hippocampus) and that precedes the upregulation of GR after 2 weeks or longer depending on antidepressant dose and route of administration. Recent studies have suggested that MDR PGP can regulate corticosterone access to the brain and HPA activity in rats and mice. Transgenic mice with deletion of the MDR PGP genes (two isoforms are found in rodents) show increased access of corticosterone to the brain and increased negative feedback on the HPA axis by corticosterone. Although the antidepressant clomipramine has been shown to regulate the intracellular levels of cortisol by inhibiting membrane steroid transporters in fibroblast cells and rat primary neurons in culture, whether this occurs *in vivo* remains to be determined.

Thus, antidepressants via a variety of mechanisms facilitate GR and MR function and hence reduce HPA overactivity. The importance of the mechanisms in antidepressant and other potential therapeutic effects is the subject of active study.

Introduction

Findings in Healthy Subjects

Preliminary Findings on HPA Axis in Psychiatric Disorders

Future Research

Glossary

<i>Canrenoate</i>	Antimineralocorticoid agent for use in humans. Potassium salt of canrenone. Active metabolite of spironolactone.
<i>Hippocampus</i>	Part of the limbic system of the brain. Involved in endocrine, emotional, and cognitive functions.
<i>Hypothalamic-pituitary-adrenocortical (HPA) Axis</i>	Major stress-mediating endocrine system in humans. Activation results in the release of cortisol from the adrenal glands. Regulated by suprahypothalamic neural influences, hypothalamic release of corticotropin-releasing hormone, pituitary release of adrenocorticotrophic

Major depression

Mineralocorticoid receptor

Posttraumatic stress disorder

Spironolactone

hormone, and negative feedback effects of cortisol.

Psychiatric illness with markedly depressed mood, considerable loss of interest or pleasure, and several other psychopathological symptoms, such as insomnia, reduced appetite, fatigue, feelings of guilt or worthlessness, diminished ability to concentrate, and suicidal ideation.

Intracellular receptor molecule with high affinity for cortisol, corticosterone, and aldosterone. Found in the central nervous system, primarily in the hippocampus and, furthermore, peripherally in the kidney.

Psychiatric illness that can occur after severe psychological trauma. Characterized by re-experiencing the traumatic event, avoidance of stimuli associated with the trauma, and persistent hyperarousal symptoms, such as exaggerated startle response, hypervigilance, difficulty concentrating, and reduced sleep.

Antimineralocorticoid agent for use in humans. Spironolactone undergoes extensive metabolism in humans: taken orally, up to 58% of spironolactone is excreted as canrenone, canrenoate ester glucuronide, and several sulfur-containing and polyhydroxylated metabolites.

Introduction

Preclinical findings have established that hippocampal mineralocorticoid receptors (MRs) control the inhibitory tone of this limbic structure on the hypothalamic-pituitary-adrenocortical (HPA) axis in terms of both basal activity and stress-evoked reactivity. Hippocampal MRs (type I corticosteroid receptors) have a considerably higher affinity for cortisol, the physiological ligand in humans, than glucocorticoid receptors (type II corticosteroid receptors); thus, they are highly occupied throughout the circadian variation of HPA axis activity. While glucocorticoid receptors are widespread in the central nervous system, MRs in brain are primarily localized in the hippocampus. Also the prereceptor metabolism of corticosteroids regulated by 11β -hydroxysteroid dehydrogenases (11β -HSD) is important for the saturation of hippocampal MRs by cortisol. While 11β -HSD type 2 in the kidneys results in selectivity of distal nephron MRs for aldosterone by inactivation of cortisol, 11β -HSD type 1 in the brain regenerates active glucocorticoids that bind to MRs in the limbic system.

The hippocampal MR is quickly upregulated by psychological stressors in rodents, such as forced swimming or novelty. This effect can be prevented by intracerebroventricular pretreatment with an antagonist for the corticotropin-releasing hormone (CRH). Thus, the MR participates in adaptive mechanisms in the central nervous system evoked by stressful events. Furthermore, aspects of anxiety-like behavior are modulated by the MR, as shown in different animal models. Our understanding of MR action upon HPA axis regulation in humans may be relevant not only for the physiology of the stress response, but also for the pathophysiology of disorders in which HPA axis alterations have been described. Given the high occupation of the hippocampal MR during both baseline and stress conditions, antimineralocorticoid challenge has been the method applied to assess MR function in humans. In human challenge studies, spironolactone and canrenoate have been used as safe antagonists at the MR that display sufficient specificity and penetrate the blood-brain barrier.

Findings in Healthy Subjects

Basal Activity of the HPA Axis

Most studies have shown elevated basal plasma cortisol concentrations as soon as 1 h after administration of spironolactone (200–400 mg orally) or canrenoate (2×200 mg intravenously). Findings about elevated plasma adrenocorticotrophic hormone (ACTH) are

less consistent, because cortisol released by the anti-MR challenge can mask this effect by an activation of the negative glucocorticoid receptor-mediated feedback at the pituitary. The significant effect of spironolactone on cortisol secretion was demonstrated with no diurnal differences between morning and evening administration despite a circadian variation of MR upregulation.

The stimulatory action of anti-MR challenge upon HPA activity can be blocked by the benzodiazepine receptor agonist alprazolam via hippocampal and hypothalamic γ -aminobutyric acid (GABA) receptors. Furthermore, the physiological inhibition of pituitary-adrenal secretion in humans during early nocturnal epochs of non-REM sleep was reported to disappear after acute antimineralocorticoid blockade.

Activated HPA Axis

Both after CRH stimulation and after stimulation with arginine vasopressin, as well as in a combined dexamethasone suppression/CRH stimulation test and during exercise, significant elevations of plasma cortisol after prior anti-MR treatment vs. placebo have been reported. These evidence a shift in set point for cortisol feedback inhibition of the HPA axis toward higher cortisol levels. Thus, MRs can modulate effects of both pituitary and suprapituitary stimuli upon human HPA axis activity.

Basal Activity of the HPA Axis in Elderly Subjects

In a circadian study, Heuser et al. demonstrated that, compared to young subjects, spironolactone treatment had stronger stimulatory effects on basal cortisol secretion in the elderly. A decrease in hippocampal MR capacity during aging might contribute to feedback alterations of the HPA system described in the elderly.

Preliminary Findings on HPA Axis in Psychiatric Disorders

Major Depression

Young et al. applied spironolactone challenges to patients with major depression. They hypothesized a decreased MR activity, because major depression is often accompanied by increased cortisol secretion and decreased dexamethasone suppression, furthermore, because glucocorticoids are capable of down-regulating MR and glucocorticoid receptors. Instead, in patients with major depression increased functional activity of the MR was found with a more pronounced cortisol and ACTH secretion after spironolactone, which is so far not sufficiently understood.

Posttraumatic Stress Disorder (PTSD)

Kellner et al. investigated whether findings of diminished basal and stress-induced cortisol output reported in PTSD could be caused by an enhanced MR activity. In contrast to expectation, spironolactone effects upon basal and CRH-stimulated HPA axis were indistinguishable in PTSD patients and healthy controls. However, underlying the experimental conditions, other compensatory factors, such as hyperactive pituitary glucocorticoid receptor-mediated negative feedback in PTSD, might have masked the putative mineralocorticoid receptor changes.

Future Research

Future antimineralocorticoid challenge studies in humans might use new substances with higher specificity for the MR than spironolactone and canrenoate, e.g., eplerenone. An additional pretreatment with a glucocorticoid receptor antagonist would help to disentangle secondary glucocorticoid-mediated feedback effects on HPA axis activity after MR blockade. However, antiglucocorticoids, such as mifepristone and onapristone, exert effects also at other steroid receptors, such as progesterone receptors, which would complicate the allocation of steroid effects.

An alternative approach to assessing MR function is a newly developed test that uses, for the first time, not an MR antagonist, but an MR agonist after prior depletion of the endogenous cortisol from the MR using metyrapone pretreatment. Metyrapone inhibits peripherally and centrally the synthesis of cortisol via 11- β -hydroxylase and 11- β -hydroxysteroid dehydrogenase type 1.

Given animal data for the potential role of the MR in depression and anxiety, the neuropsychological and behavioral effects of antimineralocorticoid challenge in humans also require detailed research. Preliminary results by Hundt et al. show that subchronic spironolactone comedication impedes the effect of treatment with the antidepressant amitriptyline in patients suffering from major depression, whereas upregulation of MR by depletion of corticosteroid with metyrapone enhances antidepressive effects. Thus, intact MR function seems to be important for antidepressant drug action, and antimineralocorticoid challenge might be also be useful for the prediction of psychotherapeutic drug effects in patients suffering from psychiatric disorders.

Glossary

<i>Antipsychotic drugs (APDs)</i>	A diverse range of compounds central to the treatment of psychosis, mania, agitation, behavioral disturbance and sleep disturbance in psychiatric, neurological, and other medical disorders. They are divided into typical and atypical classes depending on whether they have a high (typical) or low (atypical) propensity to induce extrapyramidal side effects.
<i>Dopamine</i>	A catecholamine neurotransmitter central to reward processes and psychiatric disorders. It binds to five receptors numbered 1 to 5, the dopamine D2 receptor is thought to be most relevant to antipsychotic drug action.
<i>Extrapyramidal symptoms</i>	A varied set of distressing and disabling motor side effects induced by antipsychotic drugs binding to dopamine D2 receptors in the striatum of the brain.
<i>Schizophrenia</i>	A serious psychiatric disorder affecting approximately 1% of the population characterized by psychotic symptoms such as hallucinations and delusions, negative symptoms such as social withdrawal, loss of motivation, loss of emotion and impairments in cognition.

Introduction

Antipsychotic drugs (APDs) are a chemically diverse range of compounds that form the cornerstone of current treatments for schizophrenia and related psychotic disorders; bipolar affective disorder; and psychosis or agitation in any psychiatric, neurological, or general medical disorder. They have transformed the practice of psychiatry allowing the closing of large scale institutions and the return of patients to community based treatment. In the United States in 2005, they were the 20th most dispensed class of agent with 43.8 million prescriptions but were the third largest by sales value.

This prominence belies their entirely serendipitous development. The first antipsychotic, chlorpromazine, was synthesized in 1950 by Paul Charpentier as a preanesthetic sedative based upon the antihistamine, promethazine. Its use in 1951 by the French surgeon, Laborit, resulted in his observation of patients displaying a strong indifference to the environment in the presence of full consciousness which he termed artificial hibernation. Chlorpromazine was introduced into psychiatry in 1952 by Delay and Deniker and it revolutionized the treatment for schizophrenia, other psychotic disorders, and agitation leading to the spawning of numerous chemically related phenothiazine compounds. Paul Janssen discovered the next class of antipsychotic agents, butyrophenones, also serendipitously when developing analgesics derived from meperidine. These agents, which include haloperidol and droperidol, are structurally dissimilar to phenothiazines but possessed similar clinical efficacy despite being much more potent and likely to induce distressing and disabling motor side effects termed extrapyramidal symptoms (EPS).

Clozapine, a dibenzazepine, was synthesized in 1958 and is distinct from other APDs in not inducing EPS. It was also subsequently noted that clozapine appeared to be effective for patients who were otherwise unresponsive to APDs. It was, however,

withdrawn following its association with cases of fatal agranulocytosis in the early 1970s. A re-evaluation of clozapine and in particular its effectiveness in treatment-resistant patients with schizophrenia led to its re-introduction under strict hematological monitoring in the late 1980s.

This capacity of clozapine to be effective in schizophrenia and related psychotic disorders whilst not inducing EPS stimulated the development of a new generation of APDs, the so-called atypical or second-generation APDs. These atypical APDs currently include risperidone, olanzapine, quetiapine, amisulpride, ziprasidone, aripiprazole, sertindole, and zotepine, which in the developed world have very much replaced the first generation or typical phenothiazine, butyrophenone, and similar APDs.

This article will discuss the pharmacology of APDs and their proposed mechanism of action with particular reference to the difference between atypical and typical agents. A brief description of their clinical effects will follow and a section of the interaction of APDs with stress systems will conclude the article.

Mechanism of Action of Antipsychotic Drugs

The ongoing debate about the mechanisms of action of APDs underscores the heterogeneity of their pharmacology. The vast majority of APDs have multiple receptor affinities involving numerous neurotransmitter systems. These systems include dopamine, serotonin, muscarinic acetylcholine, norepinephrine (norepinephrine), and histamine. Disentangling sites of action relevant to clinical outcomes remains an ongoing and central task for the development of better therapeutics.

The original critical observation in understanding how APDs worked was that treatment with APDs in mice resulted in an increased turnover of monoamines in brain tissue. The relevant monoamine was specifically identified as dopamine and this was supported by clinical evidence implicating dopamine as psychotogenic. In particular, drugs that induced dopamine release, including amphetamine and cocaine, or stimulated dopamine production, levodopa, caused psychotic symptoms in control subjects and exacerbated psychotic symptoms in patients with stable schizophrenia. The search for dopamine's germane target led to the identification of the dopamine D2 receptor (DAD2R) and the evidence supporting the DAD2R as the main site of action of APDs is now powerfully robust. These data include: the close correlation between the K_i value for the DAD2R for each drug and its clinically effective dose; the

therapeutically effective APD, cis-flupenthixol, pharmacologically differs to its clinically ineffective trans isomer only in its much greater potency as a DAD2R antagonist; no antipsychotic has been identified to date that does not have significant antagonism for the DAD2R; and neuroimaging studies in people with schizophrenia demonstrate greater than 65% occupancy of DAD2R in the striatum is necessary and sufficient for antipsychotic response. However, blockade or loss of the DAD2R in the striatum is also known to induce EPS. Thus, how atypical APDs like clozapine were effective yet with low or no propensity to induce EPS presented a paradox.

Theories of Atypical Antipsychotic Drug Action

How atypical APDs are effective in the treatment of psychotic symptoms but do not induce EPS has not been definitively established. Neuroimaging studies indicate that the EPS syndromes of Parkinsonism and akathisia are induced by striatal DAD2R occupancies of approximately 78% or higher while therapeutic efficacy as stated above occurs with striatal DAD2R occupancies of approximately 65–70%. Parenthetically, it is unlikely that striatal DAD2R occupancy is directly relevant to antipsychotic action but is used as a proxy measure for DAD2R occupancy in other more relevant brain regions. A number of theories have been proposed to explain why atypical drugs are able to achieve striatal DAD2R occupancy levels commensurate with therapeutic efficacy but not cross the EPS threshold and these will be reviewed briefly below.

The Serotonin 5HT_{2A} Receptor

Using the prototypical atypical APD clozapine, investigators have focused upon its receptor binding profile in an attempt to understand the mechanisms underpinning its atypical properties. Its high affinity for the serotonin 5HT₂ and more specifically the 5HT_{2A} receptor led to the proposal that antagonism at this receptor at therapeutic doses may underlie atypicality by modulating DAD2R occupancy in the striatum and by participating in antipsychotic activity. However, as chlorpromazine and other typical drugs also have high affinities for this receptor, this was refined to a relatively greater affinity for the 5HT₂ compared to the DAD2R expressed as a ratio for each drug. It received support from both *in vivo* and *in vitro* data demonstrating serotonin 5HT₂ receptor-induced increases in dopamine release in the striatum and preliminary reports of clinical efficacy of 5HT_{2A} receptor antagonists.

Much evidence now exists, however, to indicate that 5HT_{2A} receptor antagonism is neither necessary nor sufficient for an APD to exhibit atypical properties. Most critical is that the clinically effective APDs remoxipride and amisulpride do not induce EPS at therapeutic doses but have minimal affinity for the 5HT_{2A} receptor. Using positron emission tomography (PET) neuroimaging, chlorpromazine binds to 65% of cortical 5HT_{2A} receptors at a clinical dose of 500 mg that induces EPS and risperidone at a moderately high clinical dose of 6 mg occupied 95% of 5HT_{2A} receptors but induced EPS in six of seven subjects indicating that 5HT_{2A} receptor occupancy does not ameliorate EPS clinically. This clinical data is also supported by animal data minimizing the relevance of 5HT_{2A} receptor occupancy in reducing EPS.

With respect to the role of 5HT_{2A} receptor antagonism in APD efficacy, it appears similarly unnecessary: as noted above both atypical and many typical APDs do not exhibit affinity for the 5HT_{2A} receptor; 5HT_{2A} receptor antagonists without appreciable affinity for the DAD2R (e.g., ritanserin or MDL 100907) do not have antipsychotic efficacy; PET studies of therapeutic efficacy in schizophrenia demonstrate that the obligatory DAD2R occupancy threshold of 65% is irrespective of 5HT_{2A} receptor occupancy; and high levels of 5HT_{2A} receptor blockade occur at subtherapeutic doses of risperidone, clozapine, olanzapine, and quetiapine.

A further elaboration has been the proposal that inverse agonism at the 5HT_{2A} receptor may contribute to antipsychotic effect. However, both amisulpride and remoxipride do not possess this property and MDL 100907 is a potent 5HT_{2A} receptor inverse agonist but is not an APD suggesting this is also not relevant to the efficacy of APDs.

The Dopamine D3 and D4 Receptors

Similar structurally to the DAD2R, the dopamine D3 and D4 receptors (DAD3R and DAD4R), also bind intracellular inhibitory proteins (Gi/o) thereby inhibiting adenylyl cyclase and thus the three receptors comprise the dopamine D2-like class of dopamine receptors. The high affinity of clozapine for the DAD4R, led to the postulation that binding to this receptor was responsible for its antipsychotic properties while its lower DAD2R occupancy explained its absence of EPS. However, haloperidol and other typical APDs have similar affinities as clozapine for DAD4R and a relatively specific DAD4R antagonist, L-745870, was without antipsychotic effect. Thus, there is little support to date for DAD4R in the action of APDs or in explaining atypical effects.

The pharmacological similarity of DAD3R to the DAD2R and its localization to the mesolimbic

dopamine system, a brain circuit closely implicated in the pathology of schizophrenia have offered it a possible role in the pathology of schizophrenia and action of APDs. The evidence for this includes the high affinity that many typical and atypical APDs exhibit for the DAD3R including the relative specificity of amisulpride as an antagonist for DAD2R and DAD3R implicating DAD3R in explaining its atypical properties. Conversely, clozapine has low affinity (K_i 500 nM) for the DAD3R suggesting that DAD3R antagonism is not necessary for either APD action or in atypicality. The long availability of specific DAD3R antagonists yet the absence of any clinical data in schizophrenia implies the absence of any striking clinical utility, although this awaits publication.

Limitations of the Dopamine D2 Receptor Hypothesis

The weakness of evidence supporting 5HT_{2A}, D3, or D4 receptors in the mechanism of atypical APD action should not entail that the DAD2R hypothesis is flawless. Single photon emission tomography (SPECT) neuroimaging studies demonstrate that some subjects with schizophrenia responded to APD treatment at striatal DAD2R occupancy rates well below 65% and some did not respond with occupancy rates over 90%. Moreover, PET studies of clozapine, and more recently quetiapine, only reached striatal DAD2R occupancies of 0–59% at clinically effective doses indicating that DAD2R occupancy might not be essential for APD efficacy.

Two major hypotheses have been proposed to explain why low striatal DAD2R occupancy rates are congruent with clinically effective doses of clozapine and quetiapine while retaining the centrality of the DAD2R in the mechanism of APD action. One postulates that clozapine and quetiapine at clinically relevant doses preferentially bind to cortical (principally temporal cortex including amygdala and hippocampus) over striatal DAD2R in subjects with schizophrenia. The other proposes that drugs like clozapine and quetiapine dissociate rapidly from the DAD2R. Here, the APD occupies the DAD2R either *in vivo* or *in vitro* immediately it is introduced but within minutes *in vitro* or hours *in vivo* dissociates from the receptor. This contrasts with typical APDs where there is a many fold longer time of binding between drug and DAD2R both *in vivo* and *in vitro*. The rapid dissociation of clozapine and quetiapine from the DAD2R allows the receptor to then be activated by the release of endogenous dopamine ameliorating any EPS.

Neither explanation is incontrovertible, thus the centrality of DAD2R antagonism in APD action is not infallible given the above anomalies in the data. However, it remains the most plausible of hypotheses and at this time there does not seem an overwhelming need to invoke other receptor systems to explain the basic actions of APDs nor the difference between atypical and typical agents. This, of course, does not imply other receptor systems such as the DAD3R, glutamate, γ -aminobutyric acid (GABA), serotonin, acetylcholine, or other neuromodulatory systems may not be involved, and in fact may be involved in other properties of APDs, however, their role in primary antipsychotic efficacy remain to be established.

Partial Dopamine D2 Receptor Agonism

A variant hypothesis to DAD2R antagonism is partial agonism at this receptor based on animal studies of the pharmacology of aripiprazole as the leading exemplar of its class. Both short- and long-term clinical trials of aripiprazole demonstrate it to be an effective APD with low EPS. In animal models where dopamine hyperactivity is present (e.g., apomorphine-induced stereotypy) aripiprazole functions as a DAD2R antagonist, however, in models of dopamine depletion (e.g., reserpine treatment) it exerts a partial agonist activity. Thus it could be effective by functioning as a relative antagonist on DAD2R signaling pathways relevant to psychosis yet permit sufficient dopamine signaling in the striatum to prevent EPS.

What Happens After the Dopamine D2 Receptor?

Although APD binding to the DAD2R appears to be central to their mechanism of action, this can be only a first step in modifying neuronal activity. This is congruent with the time between onset of receptor blockade within 1 hour and clinical efficacy which takes days to weeks. The most plausible sequence of events center on the time required for inhibition of the DAD2R coupled Gi/o protein to result in activation of adenylyl cyclase, increase cyclic AMP levels, and activate protein kinase A (PKA). PKA activation, in addition to phosphorylation of other kinases, receptors, and ion channels, activates transcription factors including the cyclic AMP response element binding protein (CREB). These transcription factors in turn regulate gene expression of receptors, neuropeptides, and synaptic proteins ultimately resulting in *de novo* protein synthesis some days to weeks after initial receptor blockade. It is important to consider, however, that other signaling pathways are also linked to

the DAD2R and their relevance cannot be excluded. Less clearly established is the identity of key proteins regulated through the above signaling pathways and how they effect changes in neuronal function leading to antipsychotic effects. Observations of regional brain differences in activation of immediate early genes between typical and atypical APDs may give direct clues as to which proteins in which brain regions are responsible for EPS and which proteins mediate APD efficacy.

One set of proteins implicated in APD activity involve synaptic plasticity and connectivity. These proteins are decreased in schizophrenia and increased in animals treated with typical and atypical APDs. This raises the possibility that APDs may stimulate synaptic reorganization. It remains to be determined whether such changes occur in humans when responding to the clinical effects of APDs.

The Clinical Role of Antipsychotic Drugs

As noted above, APDs are used in the treatment of a diverse range of psychiatric, neurological, and medical disorders where short term they control psychotic symptoms such as hallucinations and delusions and also agitation and behavioral disturbance. These symptoms are the cardinal features of schizophrenia and related psychotic disorders but may also be observed in bipolar affective disorder, substance-induced states, major depression with psychosis, dementia, delirium, posttraumatic stress disorder, borderline personality disorder, a variety of neurological disorders including Huntington's disease, multiple sclerosis, Parkinson's disease, temporal lobe epilepsy, and medical disorders including endocrine, metabolic, autoimmune, and neoplastic disorders. Furthermore, APDs are effective in long-term prophylaxis of relapse of psychosis in schizophrenia and related disorders and potentially bipolar affective disorder.

As discussed above, the defining difference between typical and atypical APDs is the low or absent propensity of the latter to induce EPS. Nevertheless, the effectiveness of clozapine in treatment-resistant patients with schizophrenia has generated much interest as to other clinical differences between typical and atypical agents. First, there are unequivocal data showing clozapine is superior to typical APDs in treatment-resistant patients but there are now emerging data that clozapine is also superior to other atypical agents. Second, there are less well established reports in patients with schizophrenia demonstrating clozapine to be effective in suicidality; cognitive dysfunction (e.g., working memory, attention, and verbal fluency); negative symptoms (e.g., social withdrawal, lack of motivation and diminished states of feeling),

and substance abuse. The superiority of clozapine in these symptom domains is, however, far from established. Moreover, current evidence would suggest that apart from the effectiveness of clozapine in treatment resistant schizophrenia, there is no clear difference in efficacy between typical and atypical APDs.

Befitting the chemically diverse range of compounds that constitute APDs, the side effect profiles of these agents are varied. The reduced propensity for atypical APDs to induce EPS has been noted and is an advantage for this group over typical APDs. However, the risk is not absent and needs to be offset against other adverse effects. In addition, prolactin and other endocrine effects and cardiac rhythm disturbances are commonly associated with both typical and atypical APDs. A burgeoning area of concern is the association of APDs with the metabolic syndrome, characterized by weight gain and central obesity, hyperlipidemia, hyperglycemia, insulin resistance, and diabetes mellitus type 2 and the increased risk of cardiovascular morbidity and mortality. This has been especially linked to clozapine and olanzapine but may also apply to chlorpromazine and other typical APDs. Furthermore, the association of clozapine with agranulocytosis (1%), epileptic seizures (dose dependent at 5% 600 mg day⁻¹), myocarditis (0.05%), and cardiomyopathy (0.01%) indicates the potential toxicity of these agents. This range and extent of toxicities of APDs highlight the importance of individual monitoring and detailed discussion between physician, patient, and carers when making decisions about APD treatment options.

Interactions between Antipsychotic Drugs and Stress

The interaction between stress hormones and pathways and the major psychiatric disorders such as schizophrenia, bipolar affective disorder, and major depression that are treated with APDs are well described. This has led to explorations into the modulation of stress hormone systems, especially the hypothalamic-pituitary-adrenal (HPA) axis, by APDs and in particular if differences exist between typical and atypical APDs. Hence, it has been proposed that such differential effects may invoke differences in treatment outcomes based upon the effects of HPA dysregulation on the pathology of schizophrenia. Some support for this exists with clozapine, olanzapine, and risperidone but not haloperidol decreasing cortisol and/or adrenocorticotrophic hormone (ACTH) levels and this being associated with changes in psychopathology. Furthermore, studies in healthy subjects found no effect on cortisol levels by the

typical APDs, haloperidol and sulpiride but decreases with olanzapine and quetiapine. In contrast no effect on cortisol levels was observed with amisulpride, an atypical APD with relative specificity for DAD2R and DAD3R.

The regulation of ACTH by monoamines including serotonin and dopamine imply that all APDs should influence ACTH and cortisol levels. However, the decrease in these levels in both control and schizophrenic subjects by atypical APDs has been proposed to be attributable to 5HT_{2A} receptor antagonism. In support of this is the observation that the 5HT_{2A} receptor antagonist, ritanserin, attenuated increases in psychotic symptoms and plasma cortisol levels in schizophrenic patients administered the serotonin agonist *m*-chlorophenylpiperazine. Similarly, the relatively high affinities for the 5HT_{2A} receptor for clozapine, olanzapine, quetiapine, and risperidone but the low affinity of amisulpride is also consistent with this proposal. However, it is also feasible that the attenuation in cortisol and ACTH by atypical APDs could also be attributable to their adrenergic or histaminergic receptor affinities.

The clinical relevance of atypical APDs induced decreases in cortisol and ACTH plasma levels needs further investigation. Two reports have observed a correlation between cortisol levels and negative symptoms in schizophrenia; however, this was not correlated with the dose of risperidone and was not observed in another study. Of greater interest are the relationships of the HPA axis to depressive disorders and the potential role of atypical APDs in these disorders. Here it may be that downregulation of the HPA axis by atypical APDs and the reduction in glucocorticoids may have a beneficial effect on mood and warrants further investigation.

Conclusions

APDs provide the major plank in the treatment of many psychiatric and neurological disorders. The division into atypical and typical classes is based upon their relative propensities to induce unwanted and disabling extrapyramidal motor side effects. Despite their generally widespread monoamine receptor affinities, both antipsychotic efficacy and propensity to induce EPS may be explained by their antagonism at the DAD2R and does not require the invocation of other systems. However, the challenges remain in determining specifically how atypical agents occupy less DAD2R in the striatum while exerting an antipsychotic effect and, moreover, as for all APDs, characterizing what post-DAD2R pathways are essential for antipsychotic efficacy. Furthermore, the unique

clinical profile of clozapine does present etiological challenges to the DAD2R hypothesis and understanding the reasons for its effectiveness in treatment-resistant schizophrenia holds promise for improving the outcomes for this and other disorders. Finally, as the modulation by APDs of systems such as serotonin, acetylcholine, norepinephrine, histamine, the HPA axis, and others is further studied it may become feasible to expand and better target the role of these drugs in the treatment of particular symptoms and disorders.

Prevention and Treatment

Glossary

Antisocial personality disorder (ASPD)

Personality disorder characterized by frequent violation of social and legal norms, grandiose thoughts, arrogance, manipulative behavior, superficial charm, lack of attachment to others, little empathy, and an absence of guilt. Synonyms are sociopathy, psychopathy, and dyssocial personality.

Conduct disorder (CD)

Behavior disorder of childhood and adolescence characterized by truancy,

	stealing, running away, fighting, vandalism, fire setting, sexual assault, or other illegal activities.
<i>Continuity</i>	A term used in developmental psychopathology to refer to behaviors that continue from one stage of life to another, e.g., from adolescence to adulthood.
<i>Desistance</i>	A term used by criminologists to describe the cessation of criminal activity in a person who has previously committed illegal acts.
<i>Developmental psychopathology</i>	A field of study that focuses on the development and longitudinal course of psychiatric disorders across the life cycle.
<i>Discontinuity</i>	A term from the field of developmental psychopathology referring to behaviors that do not persist from one life stage to another.
<i>Escalation</i>	A term used in criminology to describe an increase in the frequency of illegal acts or an increase in the severity of such behavior over time.

Definition

Clinical Example

A.W. is a 40-year-old male who was released from prison 6 months ago. This was his second prison term; both terms had been served for burglary. A.W. was first sent to prison for 3 years when he was 25 years old. He had been working as a security system installer. He would install an alarm system and then return later and rob the house. A.W. proudly says that he robbed more than 800 houses in a 3-year period. After he served his first sentence, he learned how to open safes. He did several large jobs in houses and businesses before getting caught and sent back to prison for 10 years.

A.W. has a history of violence, consisting of fights in bars and on the street with other men, and fighting with his wife and girlfriends. His family believes he may have murdered his first wife and successfully hidden the body, but this has never been proven. A.W. openly admits that he initiates violence because he is bored or irritated. He himself was a childhood victim of severe violence perpetrated by his alcoholic father, who would also attack A.W.'s mother. He reports that he was beat many times with his father's hands and fists, as well as with a belt, board, and electrical cord. He suffered multiple episodes of head trauma. A.W. started fighting peers when he was 12 and hit his father for the first time when he was 14.

School was not easy for A.W., and he had numerous learning problems. He left school in the seventh grade at the age of 15 and joined the Army, using

his dead brother's Social Security number. Testing in the Army revealed that he was bright and actually was functioning on a 12th grade level, but he got into so many fights that he eventually received a dishonorable discharge.

A.W.'s health is not good. He suffered his first grand mal seizure while in prison 10 years ago. He now has them regularly, despite medication. He has chronic bronchitis and hypertension. He used to drink heavily, but stopped 10 years ago when put back into prison, and reports that he will not drink again. He denies any drug use other than early experimentation with marijuana.

There have been several long-term female relationships in A.W.'s life, although he has had multiple brief liaisons. He has seven children, born to three different women. His first wife disappeared after the birth of their second child, and it was widely known that A.W. was angry because he thought she was seeing another man. He has had two other important relationships, and both these women have complained that he was physically abusive. He denies being abusive to his children, but has not been home enough to actually parent them. He reports sadness about that, as four of his children are in foster care.

Classification of Antisocial Disorders

The adult syndrome of antisocial personality disorder (ASPD) was first described by Harvey Cleckley in his famous book *The Mask of Insanity*. Cleckley's original characterization of interpersonal, behavioral, and affective deviance has remained the core of subsequent diagnostic criteria. As exemplified by A.W.'s history, people with this disorder are narcissistic, superficially charming, manipulative, often aggressive, and short-tempered; have multiple, unstable relationships; lack empathy and guilt; and display irresponsible behavior, often with overt criminality. The *Diagnostic and Statistical Manual*, 4th edition (DSM-IV) has defined ASPD as a persistent pattern of behavior that does not take into account the rights of others or that seeks to do overt harm to others. Criteria include an inability to maintain a stable relationship or employment, irresponsible behavior such as avoidance of financial obligations or parenting duties, cruel behavior toward animals or humans, and repeated arrests (or illegal activities, even if not caught). The *International Classification of Diseases*, 10th edition (ICD-10) has similar criteria for dis-social personality. Most adults with ASPD began to display deviant behavior in childhood or adolescence. Youths with three or more of the following symptoms by age 13 are classified in the DSM-IV as having

conduct disorder (CD): stealing with or without confrontation with the victim, running away, acts of cruelty or bullying, fighting, truancy, forcing someone into sexual relations, carrying or using a weapon, vandalism, and arrests.

Psychiatric diagnoses are traditionally made through clinical interviews, interviewer-rated symptom questionnaires, or self-report questionnaires. Each of these methods is difficult to use with the person who has antisocial personality features. These patients are rarely suffering or complaining of symptoms. In fact, in a brief interaction such as an examination, they may be quite charming and engaging. They are often puzzled as to why a psychiatric evaluation has been requested and usually blame others for their actions. Self-report inventories are problematic because of the high rate of lying in this population. The two most frequently used methods of assessment are highly structured interviews that follow strict diagnostic criteria such as those found in DSM-IV or the Hare Psychopathy Checklist (PCL). Filling out the PCL requires the use of multiple sources of information, rather than just using a clinical interview.

Epidemiology

The estimated prevalence of CD in prepubertal children is between 2 and 8% for boys and is less than 2% for girls. The gender gap narrows in adolescence and rates increase, with 3–12% of boys meeting criteria for the diagnosis compared to 8–10% of girls. CD is more common in urban areas than in suburban or rural neighborhoods, but poverty is a consistent correlate.

From 5 to 15% of the general adult population may meet criteria for this disorder; in the prison populations, the estimates range from 20 to 80%. ASPD is also much more common in adult males than in females.

Development and Course

In general, most of the studies on the development and course of antisocial disorders have studied males, although more studies are now including antisocial females. The majority of the studies have also used delinquent or criminal populations, so it is often difficult to generalize findings to nonincarcerated populations.

Biological Factors

There are several major lines of research into the biological factors that may underlie antisocial behaviors. One hypothesis is that CD or ASPD is caused by a general hypoarousal of the stress response system,

producing a lack of response to stimuli that would normally provoke stress, fear, or pain. Numerous studies of men and boys with antisocial behavior demonstrate that their autonomic arousal, as measured by changes in skin conductance, heart rate, or blood pressure, is blunted in response to stimuli such as psychological threat, noise, or pain. The few studies conducted in girls have also reported blunted responses. The hypothalamic-pituitary-adrenocortical (HPA) axis also appears to be hypoactive in both the circadian secretion of cortisol and the response to psychological stimuli. These findings have been reported for boys, girls, and men who have antisocial behavior.

This lack of response would lead people with antisocial disorders to pursue excessive stimulation, manifested by sensation-seeking and risk-taking behaviors. Furthermore, they would be unable to learn from aversive consequences or punishment because their stress response would not be robust enough. Studies of heart rate, skin conductance, electroencephalogram (EEG) changes, and basal cortisol levels in subjects with antisocial behavior all support a theory of hypoarousal. Some of these characteristics in childhood and adolescence have been reported to predict adult sociopathy. Indicators of hypoarousal also differentiated between sociopathic and nonsociopathic subjects in a group of men whose fathers were all incarcerated, implying that the abnormalities in arousal may have a genetic basis.

A second line of research on putative biological mechanisms for sociopathy stems from neuropsychological and neuroimaging studies. Both types of data indicate that antisocial behavior is associated with abnormalities in the prefrontal and frontotemporal areas of the brain. These areas of the brain are responsible for the executive functions of the brain: impulse control, evaluation and integration of new data, and regulation of emotional tone and motivation. Abnormalities in these brain areas could lead to a pattern of sociopathic behavior by reducing the ability to delay gratification, decreasing the ability to learn new behaviors in response to past mistakes, and producing intense emotional states such as rage on an unpredictable basis.

Neurotransmitter function and gonadal hormonal influences on aggressive and impulsive behaviors in subjects with sociopathy have also been investigated. The findings in both domains are somewhat contradictory, but this may be due to methodological differences between studies.

In general, decreased serotonin neurotransmission in the central nervous system appears to be associated with aggression, although some researchers suggest that the link may actually be between low serotonin and impulsivity. Testosterone levels appear to be

higher in some groups of violent males, but the relationship seems to be a reflection more of dominance than of pathological aggression.

Stress

The association between stress and antisocial behavior is complex and poorly understood. Many adults and children with antisocial behavior have histories of early exposure to adverse environmental circumstances. Similarly, longitudinal studies of young children demonstrate that many of them who experience obstetrical complications, early abuse or neglect, or repeated traumatizing events develop antisocial behavior by adolescence. This is particularly true for boys.

However, both adults and children with antisocial behavior report far lower subjective stress about these events than most people experience. The stress response system hypoactivity described previously is at odds with what we know from previous clinical and animal studies about exposure to adverse events. In these studies, the resulting stress response system dysfunction is most often characterized by either normal or increased resting function accompanied by hyperreactive and prolonged responses to stimuli. These physiological changes are usually accompanied by a heightened subjective experience of distress in humans. A chronically aroused state such as this can be associated with significant physical and psychiatric morbidity (e.g., hypertension, osteoporosis, dementia, depression). Therefore, one current theory is that stress response system hypoactivity in people with antisocial behavior may be protective, allowing them to survive in very difficult environments.

Childhood Risk Factors

Several risk factors present in childhood are associated with adult sociopathy. One of the most consistent findings, whether measured retrospectively or prospectively, is exposure to inconsistent and harsh parental discipline. The severity of the punishments can range from frequent verbal shaming to overt physical abuse, but the key prognostic factor appears to be the unpredictability of the hostile parental behaviors.

Children who have attentional problems with hyperactivity seem to be at particularly high risk of developing antisocial behavior. These studies have reported the same results for boys and girls. If the child also has a low IQ and one antisocial parent, then early sociopathic behavior is quite likely.

Developmental Paths

The course or path of childhood and adolescent antisocial behavior varies from person to person, but the

continuity between this type of behavior and adult sociopathy is one of the most robust findings in clinical psychiatric research. Children who begin to display antisocial behavior prepubertally appear to be at the highest risk for severe sociopathy and progression to overt adult criminality.

Both childhood and adolescent-onset CD may progress through levels of increasing severity and frequency of the behaviors, a process known as escalation. Escalation is associated with an early onset of antisocial behavior, a history of family sociopathy, violence and aggressive behaviors, social marginalization in childhood, school failure, attention deficit and hyperactivity symptoms, and continued association with deviant peers. The behaviors may also simply cease in adolescence or early adulthood (desistence). Desistence is associated with a later onset of sociopathic behavior, an absence of aggression, a strong family structure, and early school and social success. The course of the disorder may also change when a person becomes involved with drugs or alcohol.

The majority of data on developmental paths have come from studies of males. Although less is known about females, a comprehensive review of the existing literature reported that girls with CD also appear to be at an increased risk for adult sociopathy. Additionally, many of these girls develop other psychiatric disorders and have a great deal of difficulty functioning as mothers or employees. Fewer girls progress to overt criminality when compared to boys, but many remain aggressive and destructive toward family members (e.g., their children or spouses). Researchers are in disagreement about whether a subgroup of girls exists analogous to the subgroup of boys with early-onset antisocial behavior and a particularly severe and intractable course.

Prevention and Treatment

As discussed earlier, antisocial behaviors often begin in childhood or adolescence. Once established, they are very difficult to treat. As a result, researchers in the past two decades have begun to study the effectiveness of prevention. Some innovative prevention programs have reported surprisingly good results.

Although the programs differ somewhat, they have one common feature. All of them provide services to the child in every domain of his or her life. The programs often focus on mothers identified to be at risk for producing antisocial children and work to improve maternal physical and psychological health during pregnancy or following delivery. Didactic parenting training, coupled with close supervision by a

visiting nurse, has also been helpful. Helping the mothers to establish their own support systems and showing them how to negotiate through the intricacies of the medical, welfare, and mental health systems has also been effective. The second type of preventive program focuses on assisting at-risk children in learning social skills in preschool and the community and early recognition and treatment of comorbid disorders such as attentional problems. Prevention programs that focus on whole communities of children or teens at risk have also had some success. These interventions usually occur in selected schools and consist of improving self-esteem through academic achievement or increasing prosocial behavior with game-based activities and rewards.

Standard psychiatric or psychological treatments are not very useful with patients who have antisocial disorders. The most effective treatment strategies are multimodal. Interventions that combine individual cognitive-behavioral psychotherapy, pharmacotherapy for aggression or hyperactivity, parenting training, school supervision, and anger management skills (often for the entire family) have the highest rates of success.

Once a youth has committed an illegal act and is arrested, or adjudicated delinquent, it is much harder for him or her to receive treatment rather than punishment. Data suggest that employing multimodal treatment programs, in combination with a compensation process, to atone for the offense and psychiatric treatment of comorbid disorders works better than incarceration at promoting desistance.

The same treatment dilemma exists for adults with ASPD. Those who do not engage in criminal behavior rarely present for treatment unless they are in the midst of a crisis such as a divorce. The personality characteristics of these patients make them poor candidates for psychotherapy. They may be noncompliant with any type of long-term treatment because they are only temporarily motivated to reduce the discomfort produced by the crisis. Adults with ASPD who have committed crimes do present for treatment while incarcerated, but this is usually because of comorbid psychiatric disorders such as depression. Pharmacological treatment of these comorbid problems or specific problematic behaviors such as aggression is possible, but the underlying pattern of sociopathic behavior is rarely altered.

Anxiety and Fear

Different Types of Anxiety

Anxiety and Cognition

Anxiety Disorders

The Neuroanatomy of Anxiety

Glossary

<i>Anxiety</i>	Apprehensive anticipation of uncertain, often ill-defined dangers.
<i>Fear</i>	Emotional state associated with attempts to cope with threatening events.
<i>Panic attack</i>	A sudden surge of anxiety associated with physiological symptoms (e.g., heart-rate increases) and catastrophic feelings (e.g., fear of dying) that come suddenly and seemingly unprovoked.
<i>State anxiety</i>	The level of anxiety at a defined point in time.
<i>Trait anxiety</i>	An individual's habitual level of anxiety.

Anxiety is an aversive emotional state associated with the apprehensive anticipation of more or less likely future dangers. It incorporates the somatic symptoms of tension and dysphoric feelings.

Anxiety and Fear

Anxiety is closely related to fear (see **Fear**). The traditional distinction has been that anxiety, in contrast to fear, lacks an obvious eliciting stimulus. According to the definitions given here, anxiety and fear occupy different temporal locations in relation to threatening events, anxiety typically being anticipatory to, and fear elicited by, threatening stimuli. Furthermore, whereas the threat in anxiety often is imagined, in fear it is typically real. These differences promote different phenomenologies in the two states, with anxiety dominated by an unpleasant feeling of foreboding and fear by an urge to escape. However, the perhaps most fruitful distinction can be derived from the controllability of the threat. Fear is predicated on the hope that the situation can be coped with, that it is controllable. Fear, therefore, is a source of motivation

because it supports active attempts to deal with the threat by, for example, escape or avoidance. Anxiety, on the other hand, results when the coping attempt fails, that is, when the situation is perceived as uncertain or uncontrollable. With few or inefficient means to cope with the threat, the option that is left is the apprehensive anticipation of the more or less likely expected disaster.

This analysis gives anxiety and fear a joint origin in an evolved defense system that has served through eons of time to protect organisms from survival threats. The primary emotional counterpart is fear, which supports adaptive coping with threat. However, depending on restrictions in the controllability of the situation, there is a dynamic interplay between the closely related emotional qualities of fear and anxiety. Because fear is the prototype reflected in anxiety, the two emotional states have many similarities, for example, in terms of components (aversive feelings, physiological responses, and behavior; see **Fear**). Thus, the two states may often be hard to distinguish, but this is due to the fact that they are fused in the real world rather than to conceptual obscurity.

Placing anxiety and fear at different regions of a controllability dimension has the added virtue of relating both these states to another related concept dominated by dysphoric feelings – depression. Thus, whereas fear is the emotional concomitant in situations of somewhat controllable threat, anxiety takes over when the uncontrollability of the situation undermines active coping attempts. With further and more lasting uncontrollability, coping becomes fruitless, which makes the organism helpless and replaces anxiety with depression. Thus, the conceptual view advanced here is compatible with the emerging notion of negative affect as a pervasive higher order factor behind both anxiety and mood disorders.

Different Types of Anxiety

Situational versus Free-Floating Anxiety

There are several more or less interdependent bases for distinguishing between different types of anxiety. The controllability analysis puts anxiety on a continuum between fear and depression. There are other related continua that are often invoked in this context. One is that of situational versus free-floating (generalized) anxiety. Situational anxiety is bound to a particular stimulus, such as the stimulus in phobic

anxiety. Whether anxiety of this type should be called anxiety or fear depends on the controllability of the fear stimuli in the situation. In situationally unfocused or free-floating anxiety, the intensity of the anxiety does not vary with the situation, but is always present at a noticeable level.

Panic Attacks versus Generalized Anxiety

Free-floating (generalized) anxiety is correlated with worries (e.g., about finances or academic performance). It is often contrasted with panic attacks, which have been claimed to represent a distinct subtype of anxiety. A panic attack is a sudden surge of often overwhelming anxiety dominated by physical symptoms such as shortness of breath, dizziness, palpitations, trembling, sweating, nausea, hot flashes, and chest pain. It may also involve feelings of depersonalization and fears of dying or going crazy. A panic attack may appear to be spontaneous, coming out of the blue, or to be situationally provoked. For example, a social phobic may experience panic when forced to face a threatening social context.

Some people have occasional panic attacks with no or only little residual anxiety between the attacks. However, because a panic attack is such an overwhelmingly aversive experience, the person may start to develop anticipatory anxiety about further attacks. As a result, occasional attacks will now appear against a fluctuating background of anticipatory anxiety, and the distinction between panic and generalized anxiety will become somewhat blurred.

Factor Analytically Derived Varieties of Anxiety

Factor-analytic work on observed and self-reported anxiety symptoms in normals and patients confirms clinical observations in delineating two clusters of anxiety. Thus, there is one cluster of somatic over-reactivity composed of symptoms such as sweating, flushing, shallow breathing, and reports of heart palpitations, intestinal discomforts, and aches and pains. The other cluster may be called cognitive or psychic anxiety and is composed of intrusive and unwanted thoughts, worrying, ruminations, restlessness, and feelings of muscle tension.

Trait versus State Anxiety

The distinction between panic and generalized (free-floating) anxiety is related to another important distinction. A particular person may suffer from habitually elevated anxiety, never feeling completely free of apprehension and worry. This habitually elevated anxiety is called trait anxiety. Nevertheless, the level of anxiety may still vary somewhat across time and situations. The momentary level of anxiety at a

particular time (e.g., during a panic attack), on the other hand, is called state anxiety. Even though people with high trait anxiety tend also to have high state anxiety in most situations, there may be situations in which the state anxiety of low-trait-anxious people is still higher because of stressful circumstances.

Clinical versus Normal Anxiety

Anxiety is both a phenomenon of everyday life and an important sign of psychopathology. Thus, there is a need to distinguish between normal and clinical anxiety. In general, clinical anxiety is more intense, recurrent, and persistent than normal anxiety. Furthermore, whereas normal anxiety is proportional to the real danger of the situation, the intensity of clinical anxiety is clearly above what is reasonable, given the objective danger involved, tending to paralyze individuals and undermine their coping efforts. Consequently, it results in impeded psychosocial or physiological functioning, which may promote contact with treatment facilities.

Anxiety and Cognition

To be anxious implies a preoccupation with threat and danger. For example, people with high anxiety tend specifically to overestimate the likelihood that they will experience negative events, but they do not differ from people with low anxiety in judging the likelihood that they will experience positive events. Anxiety and cognition, in fact, are intimately related to one another in a two-way communication in which anxiety determines cognition and cognition determines anxiety.

Attentional Bias for Threat

The immobility exhibited by animals that freeze in the face of danger is associated with hypervigilance to the environment. Similarly, there is a large research literature documenting that anxiety is associated with hypervigilance and an attentional bias for threat. For example, when simultaneously exposed to two visual stimuli, one threatening and the other nonthreatening, anxiety patients tend systematically to attend to the threatening stimulus, as revealed by their shortened reaction times to probe stimuli occurring at the location of the threatening stimulus. Low-anxiety people, on the other hand, tend to shy away from threat; their reaction times are faster for probe stimuli at the location of nonthreatening stimuli. This general finding is valid regardless of the threat conveyed by the pictorial (e.g., angry faces) or word (e.g., cancer) stimuli. Similarly, if people high or low in anxiety are asked to name the color in which words are printed

(the Stroop paradigm), the color-naming latency is longer for threatening than for nonthreatening words in anxious (but not in nonanxious) people. This implies that high-anxiety people are distracted by attention to the threatening word content.

The attentional bias for threatening stimuli in highly anxious research participants does not require conscious recognition of the stimuli. Several studies have shown that similar results are obtained when the threatening stimuli are presented masked by other stimuli, thus precluding their conscious recognition. For example, using the Stroop color word paradigm, longer color-naming latencies to threatening words are observed in highly anxious people, even if the word is shown only for 20 ms and immediately masked by illegible letter fragments of the same color. This finding implies that the attentional bias operates at an automatic, preattentive level of information processing. Thus, outside the conscious awareness of individuals, this attentional bias determines that they preferentially attend to threatening events in their surroundings. This preference for focusing attention on threat no doubt helps maintain the anxiety.

Expectancy and Interpretational Bias

Attentional bias provides a case in which anxiety drives cognition. However, it is also abundantly clear that cognition drives anxiety. This is particularly well documented for panic. A compelling argument can be advanced to the effect that catastrophic interpretations provide a necessary condition for the elicitation of panic. According to the dominating model, stress or anxiety results in an autonomic arousal that is perceived by the person. The perception of this bodily change prompts more anxiety and further autonomic arousal in a vicious circle. But it is only when the interpretation of the bodily symptoms becomes catastrophic (e.g., when the person feels that they signal serious illness or imminent death) that the full-blown panic attack emerges.

Several lines of evidence support this model. For example, when panic attacks are pharmacologically promoted in panic patients (e.g., through lactate infusion or CO₂ inhalation), panic is unlikely if patients are informed about the expected effects of the manipulation. If they are not informed, or misinformed, on the other hand, panic patients (but not social phobics) are likely to experience panic. Similarly, if panic patients inhaling CO₂ are led to believe that they can manipulate the CO₂ saturation in the inhaled air by pressing a panic button, this induced sense of illusory control protects them from panic attacks and decreases their self-rated anxiety. Conversely, if panic patients are led to believe through false physiological feedback that their heart is racing,

they become more anxious and show more psychophysiological arousal than control subjects.

Anxiety Disorders

Disorders of anxiety are common in the population, afflicting about one-quarter of adult individuals. One group of the anxiety disorders, phobias, is more closely related to fear than to anxiety (see **Fear**).

Panic Disorder

Recurrent panic attacks have a key position in the diagnosis of anxiety disorders, and they are what the diagnostician first looks for. Panic disorder is a condition characterized by recurring and crippling panic, typically associated with distressing worries about future panic attacks. As a result, the normal social life of the individual is compromised. Typically panic disorder occurs in the context of agoraphobia (see **Fear**), in which the person starts to avoid situations in which he or she will be left helpless and vulnerable in the event of a panic attack.

Generalized Anxiety Disorder

If the anxiety is manifested as uncontrollable and excessive anxiety and worry about events or activities (e.g., finances or school performance), generalized anxiety disorder may be diagnosed. Patients with this disorder worry more or less constantly and their worries are less controllable and more self-driven and ruminative than normal worries. Typically the worry is combined with somatic symptoms or other anxiety symptoms such as restlessness, fatigue, irritability, muscle tension, and concentration and sleep difficulties.

Posttraumatic Stress Disorder

Posttraumatic stress disorder has its origin in intense traumas, that is, in situations whose danger and aver-siveness are outside the range of usual human experience, such as in natural disasters, war, violent crime, or severe accidents. In this disorder, the traumatic event is persistently reexperienced (e.g., in the form of flashbacks), stimuli or events associated with the trauma elicit intense anxiety and are avoided, and the person feels generally numbed with regard to emotions. Common anxiety symptoms experienced by people suffering from posttraumatic stress disorder include difficulties sleeping and concentrating, irritability or outbursts of anger, hypervigilance, and exaggerated startle.

Obsessive-Compulsive Disorder

Obsessions are persistent thoughts, impulses, or images; compulsions are repetitive behaviors such as

hand washing and checking or mental activities such as praying or silently repeating words. The essential features of obsessive-compulsive disorder are recurrent, uncontrollable obsessions or compulsions that are performed with the ostensible purpose of reducing anxiety. The obsessions and compulsions are associated with marked distress, and they interfere with the normal routines, even though the victim, at least at some point, has recognized that they are excessive or unreasonable.

The Genetics of Anxiety Disorders

Statistical modeling based on comorbidity data in twins suggests that there are two independent genetic factors involved in the anxiety disorders. The anxious-misery factor is related to panic disorder, agoraphobia, posttraumatic stress disorder, generalized anxiety disorder, and depression, whereas the fear factor predisposes for specific phobias. The model suggests only a limited role for shared (within-family) environmental factors, but it suggests a substantial role for unique environmental factors (i.e., factors affecting one family member but not others) for all disorders. This genetic difference between the disorders may explain why those related to the anxious-misery factor all respond to the same medication (selective serotonin-uptake inhibitors), which is ineffective in specific phobias. It may also be reflected in psychophysiological data showing a distinct fear response in specific phobics who are exposed to their fear object or situation but normal psychophysiological resting levels. The disorders relating to the anxious-misery factors, on the other hand, show elevated resting levels and little psychophysiological mobilization during stress.

The Neuroanatomy of Anxiety

From the perspective taken here, in which anxiety is seen as a sibling of fear, it is a natural assumption that their neural substrate shows considerable overlap. A neural network for fear activation is centered on the amygdala (see **Fear**). It is an attractive notion that this circuit is sensitized and hyperreactive in anxiety states. Furthermore, there are data suggesting that a brain area closely related to the amygdala, the bed nucleus of the stria terminalis, has a downstream connection, similar to that of the amygdala, to hypothalamic and brain-stem nuclei controlling different components of fear and anxiety, such as autonomic responses and fear behavior. However,

whereas the amygdala mediates short-term fear responses to specific stimuli, the bed nucleus of the stria terminalis is more dependent on long-term contextual stimuli for its activation. This effect appears to be mediated by an abundance of receptors for the corticotropin releasing hormone (CRH; see **Corticotropin Releasing Factor (CRF)**) in the bed nucleus of the stria terminalis, which mediates the activation of the hypothalamic-pituitary-adrenal axis (see **Hypothalamic-Pituitary-Adrenal**). Thus, this opens the possibility of separable but closely related anatomical loci for fear and anxiety. Fear may be primarily dependent on the effects of specific stimuli on the amygdala, and anxiety may be primarily dependent on the effect of contextual stimuli and CRH in the bed nucleus of the stria terminalis.

Drugs Used to Treat Anxiety

Selective Serotonin Reuptake Inhibitors

Other Antidepressants

Benzodiazepines

Other Antianxiety Drugs

Glossary

<i>Antidepressant</i>	A medicinal substance used primarily to treat depression, but may have other indications.
<i>Anxiolytic</i>	A medicinal substance that allays anxiety.
<i>Benzo-diazepines</i>	A group of substances used as anxiolytics, hypnotics, muscle relaxants, and anesthetic inducers.
<i>GABA, serotonin, nor-epinephrine</i>	Neurotransmitters involved in anxiety mechanisms.

Drugs Used to Treat Anxiety

The use of anxiety-allaying drugs goes back thousands of years to the discovery that grape juice and grain mash were fermentable and that alcohol possessed psychotropic properties. The nineteenth century saw the introduction of bromides, chloral- and paraldehyde, and the barbiturates. These had the disadvantages of drowsiness, tolerance, danger in overdose, and the likelihood of dependence. The first marketed benzodiazepine was chlordiazepoxide (Librium), but well over 1000 benzodiazepines and related compounds have been synthesized, including diazepam, the most widely used of all.

Since the mid-1990s there has been a marked change in the choice of drugs for treating anxiety

disorders. Official guidelines and practice recommendations in secondary care now recognize the advantages of the selective serotonin reuptake inhibitors (SSRIs) over the benzodiazepines in the pharmacological management of patients with one of the anxiety disorders. Primary care practitioners are now following suit. Thus, the long chain of sedative use – bromides, chloral hydrate, barbiturates, meprobamate, and the benzodiazepines – is being broken, and a new class of drugs has been substituted. This reflects both the superior and the long-term efficacy of the SSRIs and the clear drawbacks of the sedatives, such as a plethora of unwanted side effects, waning of efficacy over time, and dependence and withdrawal problems.

This shift of emphasis from sedatives to drugs licensed primarily as antidepressants leads to definitional problems. Is an SSRI an anxiolytic? An anxiolytic is a medicinal substance that allays anxiety and tension. Examples include primary anxiolytics such as the benzodiazepines and buspirone, whose primary use is to treat anxiety, and secondary anxiolytics such as antihistamines and beta blockers, whose main use lies elsewhere. SSRIs can be fitted into the latter category even though they are now the drugs of choice for treating anxiety. Furthermore, in due course, more prescriptions for SSRIs may be issued for anxiety than for depression.

Selective Serotonin Reuptake Inhibitors

Background

Tricyclic compounds usually inhibit both serotonin reuptake and norepinephrine reuptake, thus being nonselective. Efforts were made to develop compounds that showed selectivity in two ways. First, they blocked the reuptake of serotonin only, and second, they did not bind to other receptors such as the cholinergic and histaminergic receptors, thereby avoiding a range of unwanted effects. Several compounds have been developed. The first was zimeldine, which was withdrawn from the market because of neurotoxicity. The next was fluvoxamine, which has indications on a wide spectrum of disorders. The

most well known of the SSRIs is fluoxetine, a long-acting compound with a half-life of over 40 h. Its demethylated metabolite, norfluoxetine, is also an SSRI and has an even longer half-life, a week or more. This means that it maintains some efficacy for a long period of time and any withdrawal reactions are delayed. Fluoxetine has gained a wide usage, particularly in the United States. Folklore concerning its effects on personality traits and personality of people who are not clinically depressed has also accrued. As a counterpoint, concern has been expressed about its widespread use as a lifestyle compound. In addition, there have been controversies about possible increase in suicidal ideation and hostile and aggressive behavior in those taking fluoxetine. These debates have meandered on for many years without any clear evidence of resolution. Fluoxetine's widespread use in individuals without distinct clinical depression may reflect subtle mood-enhancing effects in mild dysthymic patients, those with chronic low-grade depression.

Sertraline is also a widely used SSRI with a half-life of 26 h, so it is suitable for once daily administration, as are most of the SSRIs. The drawback with sertraline is that the dosage is not a fixed one, having to be attained by titration. Another controversial SSRI is paroxetine. Efficacious and well tolerated, it has been used particularly in anxiety disorders. However, its lack of efficacy in children and adolescents and its reputation for withdrawal reactions has caused concern.

Citalopram has been a successful compound in many countries. It comprises a racemic mixture, the active compound being escitalopram: this enantiomer has enhanced efficacy in both depression and anxiety. It may also have a rapid onset of action. It has therefore been suggested that the R enantiomer interferes with some of the actions of the active S compound.

Indications

Many SSRIs are licensed for one of the anxiety disorders. However, it is important to note that the initial effect of an SSRI in the treatment of anxiety may be to transiently increase the anxiety levels and frequency of panic attacks. The antianxiety effect becomes apparent after a week of treatment. Thus, the patient must be warned about this possibility. It is often the practice with anxious patients to give an initial dose that is half that of the usual initial dose for depression.

Side Effects

SSRIs can have mild sedative or stimulant effects and indeed may have these opposing effects in different patients. Thus, overall in clinical trials, about 10%

of patients complained of somnolence, and an equal number of insomnia. However, some differences can be discerned among the various members of the class: fluoxetine causes the most stimulation, paroxetine and fluvoxamine, the most sedation. Sertraline, citalopram, and escitalopram appear to be relatively neutral. Extensive laboratory assessment of the psychomotor and cognitive effects of SSRIs shows few effects, nor is memory affected. In the elderly, SSRIs can induce a persistent tremor. The SSRIs are much safer than the tricyclics. Thus, death after overdose is much less frequent, reflecting lack of effects on cardiac conduction.

The most common adverse effects of the SSRIs involve the gastrointestinal system and typically affect at least 10% of patients. Systems include nausea, dry mouth, vomiting, abdominal pain, and dyspepsia and constipation or, conversely, diarrhea. Anorexia may occur with fluoxetine, and this has been exploited to treat bulimia. The gastrointestinal side effects of the SSRIs are strongly dose related and can usually be controlled by careful adjustment of the dose.

Weight gain is not common with the SSRIs. However, sexual dysfunction including analgesia in females is well documented.

Clinical Uses

During the last few years, many large-scale, well-controlled multicenter trials comparing SSRIs to placebo in all the anxiety disorders have been published. It is now clear that the SSRIs are quite effective and tolerated in each of these disorders. The efficacy extends across the various compounds, and the SSRIs are now recommended by most expert consensus groups as the treatment of choice in each of the various anxiety disorders.

This consensus is in itself fairly remarkable and represents the clear evolution of the treatment of choice from clomipramine in obsessive-compulsive disorder and the benzodiazepines in generalized anxiety disorder (GAD) and panic disorders. The change to recommending SSRIs in GAD is a most useful change in clinical practice. The SSRIs are better tolerated (although they may have withdrawal symptoms), and they avoid the psychomotor and cognitive impairment, interaction with alcohol, paradoxical disinhibition, and dependence and withdrawal problems that attend the use of the benzodiazepines. The other shift in emphasis has been the acknowledgment that the anxiety disorders are long-term maladies and that the evidence for long-term benzodiazepine effectiveness is nugatory. By contrast, several trials showed that the SSRIs maintain their efficacy over the long term. Indeed, the recommendation for at

least 1–2 years of treatment is often incorporated in official and semi-official guidelines, which itself is a major change in emphasis. It is important that the use of SSRIs in the treatment of anxiety disorders is considered in the context of their wider management, in particular the use of cognitive-behavioral therapy to effect a more lasting improvement. However, further trials to ascertain the best use of these multiple treatments in succession and combination are needed.

Other Antidepressants

Tricyclic antidepressants have been used to treat various anxiety disorders. The most popular has been clomipramine, especially in obsessive-compulsive disorder. Imipramine was also used in panic disorder. The use of the tricyclic compounds has declined greatly because of the superior efficacy and greater tolerability of the SSRIs.

The monoamine oxidase inhibitors (MAOIs) have also shown efficacy in the treatment of various anxiety disorders. However, formal assessments are few. The use of these compounds was never widespread and has also declined with the advent of the SSRIs.

Benzodiazepines

The popularity of the benzodiazepines was related to their relative safety in overdose as compared to their predecessors. After 30 years, misgivings concerning the benzodiazepines were expressed. Their widespread use and the possibility of dependence even at normal therapeutic doses led to recommendations for the restriction of prescribing. Despite this general disapproval, some prescribers still view these drugs quite favorably.

Background

For the prescriber, two aspects of the pharmacokinetics of benzodiazepines are germane: the speed of onset of action and the duration of action. Thus, given orally, diazepam enters the brain rapidly and exerts a prompt effect in anxiety and panic states. The benzodiazepines vary greatly in their duration of action. They potentiate the inhibitory neurotransmitter, γ -aminobutyric acid.

Benzodiazepines do not act directly on GABA receptors, but on their own receptors.

Clinical Pharmacology

In normal individuals, the depressant effects of single higher doses of the benzodiazepines can be detected readily. At lower doses, however, impairment of psychological functioning is quite difficult to quantify,

and subjective effects are usually absent. In the clinical context with anxious patients and with repeated doses, impairment of functioning is more difficult to demonstrate.

Benzodiazepines have marked and quite specific effects on memory functions and interfere with episodic memory, i.e., the system concerned with remembering personal experiences. This effect is independent of any sedation or attentional impairment.

Clinical Uses

The main use of benzodiazepines is in the management of anxiety and stress-related conditions, especially by family physicians. Few differences have been found among the benzodiazepines, although their superiority with respect to placebo has been established, but only in the short term (up to 6–12 weeks).

Benzodiazepines are also effective treatments for panic disorder, preventing the episodes rather than aborting them. Alprazolam can suppress panics, but relapse and even rebound may occur when the benzodiazepine is discontinued, even if tapered off.

Unwanted Effects

The most common unwanted side effects are tiredness, drowsiness, and torpor, so-called oversedation. These effects are dose and time related, being most marked within the first 2 h after large doses. Furthermore, drowsiness is most common during the first week of treatment. Both psychomotor skills, such as driving, and intellectual and cognitive skills are affected. As with most depressant drugs, potentiation of the effects of alcohol can occur. Paradoxical behavioral responses may occur in patients taking benzodiazepines. Such events include increased aggression and hostility, acute rage reactions, uncharacteristic criminal behavior such as shoplifting, and uncontrollable weeping. Other unwanted effects include excessive weight gain, skin rash, impairment of sexual function, menstrual irregularities, and, rarely, agranulocytosis.

In pregnant women, benzodiazepines pass readily into the fetus and have been suspected of producing respiratory depression in the neonate. Finally, benzodiazepines are present in the mother's milk and can oversedate the baby. Although overdose with benzodiazepines is extremely common, deaths due to these drugs alone are uncommon.

Tolerance and Dependence

Clinically, tolerance has not been studied in any detail. However, escalation of dosage with benzodiazepines is comparatively rare. Tolerance can supervene to clinical effects in patients maintained on moderate doses of benzodiazepines. Although many chronically

anxious patients aver that they were helped by benzodiazepines, this may reflect dependence and the need to maintain their drug intake. The percentage of patients taking benzodiazepines chronically who experience withdrawal symptoms on discontinuation of medication ranges between 27 and 45%, depending on the criteria used. The mildest symptoms on withdrawal are anxiety, tension, apprehension, dizziness, insomnia, and anorexia. More severe physical dependence is manifested by withdrawal symptoms of nausea and vomiting, tremor, muscle weakness, and postural hypotension. Occasionally, hyperthermia, muscle twitches, convulsions, and confusional psychoses may occur.

Other Antianxiety Drugs

5-HT_{1A} Partial Agonists

The class of 5-HT_{1A} partial agonist compounds has a complex pharmacology. The first one, buspirone, has been available in many countries for several years. It suppresses activity in presynaptic serotonergic neurons, diminishing serotonin activity and leading to downregulation of 5-HT₂ and perhaps other 5-HT receptors. Buspirone is much less sedative than benzodiazepines, with little propensity to induce psychomotor or cognitive impairment. In formal clinical trials, buspirone proved equieffective and equipotent to diazepam. However, patients on buspirone improved more slowly. Buspirone has fewer and less severe side effects than diazepam. Headache, dizziness, and nausea are the most common complaints; they may be severe and may necessitate lowering the dosage or discontinuing the drug. Discontinuation is not accompanied by either rebound or withdrawal.

Antipsychotic Drugs

Phenothiazines, such as chlorpromazine and trifluoperazine, and a range of other antipsychotic drugs are used by some to treat anxiety. The dosage recommended is quite low, typically less than half the initial antipsychotic dose. Sometimes, even at this dosage, the antipsychotic drug is not well tolerated by the

anxious patient because unwanted autonomic effects such as dry mouth and dizziness too closely resemble their own symptoms. Even more disconcerting but uncommon are extrapyramidal symptoms such as restlessness (mild akathisia) and Parkinsonism. It is not clear if tardive dyskinesia is a real risk, but this possibility should dissuade the practitioner from the indiscriminate use of these drugs as anxiolytics.

Antihistamines

The older antihistamines penetrate to the brain and have sedative effects. Some, such as hydroxyzine, have found some favor as anxiolytics. They are not associated with a withdrawal syndrome.

β-Adrenoceptor Antagonists

Anxiety disorders are associated with a wide range of physical symptoms. In particular, palpitations, tremor, and gastrointestinal symptoms may be assuaged by low doses of a beta blocker.

Apoptotic Morphology
Glucocorticoid Receptor Signaling
Downstream Signals
Inhibitors of Apoptosis
Conclusion

Glossary

<i>Apoptosis</i>	A type of cell death that involves a programmed sequence of events leading to the elimination of unwanted cells without inducing an inflammatory response.
<i>Caspases</i>	A family of cysteine proteases that cleave substrates amplifying the apoptotic cascade.
<i>Glucocorticoid receptor</i>	A member of the nuclear hormone receptor superfamily, activated upon binding to glucocorticoid hormones, ultimately leading to activation or suppression of genes.
<i>Glucocorticoids</i>	Steroid hormones, produced by the adrenal glands, which are anti-inflammatory, and play a role in apoptosis and metabolism.
<i>Lymphocyte</i>	White blood cell involved in immune and inflammatory responses.
<i>Thymocyte</i>	A lymphocyte produced in the thymus that is a precursor of a T cell.

Apoptosis, also known as cell suicide or programmed cell death, is essential for the development and function of multicellular organisms. It is an energy requiring, highly regulated and ordered process, resulting in the clearance of individual cells in a population and ultimately serving to maintain normal cell homeostasis. Stress can disrupt cell homeostasis and promote or interfere with normal apoptosis, with steroid hormones playing a major role in what is termed the stress response. Persistent stress can lead to sustained levels of steroid hormones, in particular glucocorticoids, which can induce immunosuppression by stimulation of lymphocyte apoptosis. In this way, the immune system is probably the most adversely affected system in the body in response to stress, leading to

susceptibility to infection and disease. These issues prompt the need for a deeper understanding of the relationship between stress on the immune system and steroid hormone-induced apoptosis.

Apoptotic Morphology

There are several distinct morphological features that occur in cells undergoing apoptosis, and are evident in most cell types including lymphocytes. They include cell shrinkage which occurs due to the movement of water and ions out of the cell, membrane blebbing, flipping of phosphatidyl serine to the external side of the plasma membrane, chromatin condensation, and nuclear fragmentation. All of these events occur without loss of plasma membrane integrity, and therefore offset the inflammatory response that occurs in other types of cell death such as necrosis. Membrane blebbing, resulting in apoptotic body formation, and the externalization of phosphatidyl serines both allow for recognition of the apoptotic cell by macrophages. In this way, apoptotic cells are cleared from the body.

Glucocorticoid Receptor Signaling

The stress response ultimately leads to the release of stress hormones such as glucocorticoids, which are anti-inflammatory and immunosuppressive ([Figure 1](#)). Physiologically, the body responds to stress by stimulation of the hypothalamus in the brain leading to the release of corticotropin-releasing hormone (CRH). The anterior pituitary gland is then stimulated by CRH to release adrenocorticotrophic hormone (ACTH, corticotropin), which in turn stimulates release of glucocorticoids from the adrenal glands. The primary glucocorticoid released in mice is corticosterone, while the form in humans is cortisol.

Glucocorticoids, as well as synthetic derivatives such as dexamethasone, elicit their effect through the glucocorticoid receptor (GR), a member of the nuclear hormone receptor superfamily. GR resides in the cytoplasm and, upon binding to glucocorticoid, is shuttled to the nucleus where it induces or represses gene transcription through interactions with DNA and various transcription factors and coactivators ([Figure 2](#)). Cells deficient in GR or with a mutation in the DNA binding domain or nuclear localization sequence will not undergo apoptosis in response to glucocorticoids. This indicates a requirement for the interaction of the GR–glucocorticoid complex with DNA for the activation of apoptosis. Most lymphoid

Figure 1 The stress response can lead to immunosuppression. The physiological response to stress begins with the stimulation of the hypothalamus to release corticotropin-releasing hormone (CRH) which leads to the subsequent release of adrenocorticotrophic hormone (ACTH, corticotropin) from the anterior pituitary gland. ACTH signals the adrenal glands to produce and secrete glucocorticoids which can induce apoptosis in thymocytes and lymphocytes in the thymus and spleen.

cells are sensitive to glucocorticoid-induced apoptosis, but there are many cell types which have functional GR but do not undergo apoptosis when exposed to glucocorticoids.

Glucocorticoids can alter the expression of both proapoptotic and prosurvival genes. Although glucocorticoid-induced apoptosis is dependent on *de novo* RNA and protein synthesis, the initiating event(s) that connects to the downstream activation of apoptosis remains unclear. Several candidate proapoptotic genes are reported to be induced by glucocorticoids. Of particular interest, are several of the BH3-only proteins belonging to the proapoptotic Bcl-2 family.

Most notable are Bim (Bcl-2-interacting mediator of cell death) and PUMA (p53 upregulated modulator of apoptosis), which are upregulated by glucocorticoids in a p53-independent manner. These and other BH3-only proteins enhance the activity of the proapoptotic proteins Bax and Bak known to permeabilize the outer mitochondrial membrane leading to the release of cytochrome-c culminating in the activation of effector caspases and finally cell death. Studies show that thymocytes and mature lymphocytes that do not express Bim or PUMA are refractory to glucocorticoid-induced apoptosis. The importance of Bim and PUMA for glucocorticoid-induced lymphocyte

Figure 2 Apoptotic pathways and a model of glucocorticoid-induced apoptosis in lymphocytes. The intrinsic pathway of apoptosis is activated in response to various stimuli including stress, DNA damage, and ultraviolet radiation (UV). The signal activates the proapoptotic Bcl-2 proteins Bax and Bak which complex to form pores in the outer mitochondrial membrane resulting in the release of cytochrome-c (cyt c). This leads to the formation of the apoptosome, which is comprised of cytochrome-c, Apaf-1 and caspase-9. The apoptosome cleaves caspase-3 leading to cell death. Antiapoptotic proteins Bcl-2 and Bcl-xL block the action of Bax and Bak. The extrinsic pathway of apoptosis involves activation of death receptors (e.g., Fas receptor) that become active upon binding ligand (e.g., Fas), signaling the formation of the DISC (death-inducing signaling complex). Cleavage of caspase-8 from the DISC amplifies the apoptotic signal through cleavage of caspase-3, leading to cell death. Cleavage of Bid to tBid (truncated Bid) by caspase-8, connects the extrinsic pathway to the intrinsic apoptotic pathway. Glucocorticoids, released in the body during stress, enter the cell and are bound by the glucocorticoid receptor (GR). This complex localizes to the nucleus where it induces and/or represses a variety of genes that ultimately lead to apoptosis of lymphocytes. It is thought that the BH3-only proteins Bim and PUMA are important in glucocorticoid-induced apoptosis, enhancing the activity of Bax and Bak.

cell death was further demonstrated *in vivo* using PUMA-deficient and *Bim*^{-/-} transgenic mice. Lymphocytes from these PUMA and Bim compromised animals were refractory to dexamethasone-induced apoptosis.

Another proapoptotic gene induced by glucocorticoids is GILZ (glucocorticoid-induced leucine zipper), and is strongly upregulated in the thymus in response to glucocorticoids. GILZ reduces the expression of the antiapoptotic protein Bcl-xL followed by an increase in the activity of caspase-8 and caspase-3. This also suggests that GILZ is an initiating signal of glucocorticoid-induced apoptosis in thymocytes. Other proapoptotic genes upregulated by glucocorticoids that may be important in glucocorticoid-induced apoptosis include the G protein-coupled receptor *tdag8* (T cell death-associated gene 8), the stress response gene *dig2*, and *txnip* (thioredoxin-interacting protein). Although these genes have been identified as being upregulated by glucocorticoids, it

remains unclear as to the exact role they play in the initiation and execution of apoptosis.

Glucocorticoids can also downregulate prosurvival genes leading to enhancement of apoptosis in lymphocytes. They include genes such as *c-myc*, *c-myb*, and *c-Ki-ras*, all of which are involved in cell proliferation and survival. In addition, glucocorticoids can repress NF-κB prosurvival signaling through induction of the inhibitor protein I-κB. It is important to realize that the induction of apoptosis by glucocorticoids involves both upregulation of prodeath genes, working in concert together, and downregulation of survival genes to induce cell death.

Downstream Signals

Apoptosis can be initiated through a variety of stimuli and can proceed through the death receptor (extrinsic) or the mitochondrial (intrinsic) pathway (Figure 2).

However, both pathways have points where they intersect, enhancing the end result that is cell death. The intrinsic pathway is activated by various stimuli such as DNA damage or cellular stress, and involves interplay of both pro- and antiapoptotic members of the Bcl-2 family of proteins. The proapoptotic Bcl-2 proteins Bax and Bak are thought to complex to form pores in the outer mitochondrial membrane leading to the release of cytochrome-c which in concert with Apaf-1 and caspase-9 form the apoptosome and activate the executioner caspase-3. The antiapoptotic proteins Bcl-2 and Bcl-xL normally interfere with the action of Bax and Bak, but are disabled upon activation of apoptosis (possibly through BH3-only Bcl-2 family members). In the extrinsic pathway, death receptors are engaged upon ligand binding (e.g., Fas receptor and Fas ligand) leading to recruitment of FADD (Fas-associated death domain) and the initiator caspase-8 forming the death-inducing signaling complex (DISC), followed by cleavage of the executioner caspase-3. The extrinsic pathway can connect to the intrinsic pathway via the cleavage of the BH3-only Bcl-2 family member Bid to tBid (truncated Bid) by caspase-8. As mentioned in the previous section, the other BH3-only Bcl-2 family members Bim and PUMA enhance the activity of Bax and Bak through the action of glucocorticoids. The later stages of apoptosis include the breakdown of lamins, cytoskeleton proteins, and nuclease activation leading to internucleosomal DNA fragmentation.

It is not clear how glucocorticoids initially signal apoptosis, but it is known that there is a requirement for the activation of Bax and Bak. Bim and PUMA enhance the activity of Bax and Bak in response to glucocorticoids. In studies using Bim-deficient mice, glucocorticoid apoptosis was partially impaired compared to wild-type animals. Thymocytes derived from PUMA knock-out mice also demonstrated partial resistance to glucocorticoid-induced apoptosis. These studies emphasize the importance of Bim and PUMA as candidate proapoptotic proteins in glucocorticoid-induced apoptosis.

Inhibitors of Apoptosis

Apoptosis can be inhibited through a variety of mechanisms, mostly through the action of the antiapoptotic Bcl-2 family members and the inhibitors of apoptosis (IAP) proteins, as well as through growth factor upregulation. Bcl-2 and Bcl-xL block the interaction of the proapoptotic proteins Bax and Bak preventing the formation of pores in the mitochondrial outer membrane, and consequently the release of cytochrome-c and caspase-3 cleavage. Studies show that

the phosphorylation status of the antiapoptotic protein Bcl-2 can dictate its ability to block glucocorticoid apoptosis. IAPs can block apoptosis by directly interacting with caspases and preventing their activation. In thymocytes, glucocorticoid-induced apoptosis can be blocked by overexpression of the IAP known as X-linked inhibitor of apoptosis (XIAP). Many cytokines such as interleukin (IL)-2, -4, and -7, and interferon (IFN)- α , as well as the activation of the T cell receptor can inhibit apoptosis induced by glucocorticoids in thymocytes. In the case of IL-7, the antiapoptotic effects are attributed to its ability to enhance the expression of Bcl-2 proteins in thymocytes and mature T cells.

Conclusion

The immune system is highly prone to the effects of stress. This is primarily due to the increased release of stress hormones, specifically glucocorticoids, which initiate a signaling cascade in immune cells that can lead to cell death by apoptosis. This occurs through the GR, involving both transactivation of proapoptotic genes and transrepression of prosurvival genes. It is still unclear as to how glucocorticoids induce apoptosis, but several candidate genes and mechanisms are emerging. Further study in the area of glucocorticoid signaling is needed to fully understand the impact of stress on the immune system.

Introduction

The arterial baroreflex represents a mechanism of fundamental importance for blood pressure homeostasis, and an impairment of its cardiac and vascular influences is believed to play a role in several cardiovascular diseases. Baroreflex abnormalities have been described early in the course of diabetes mellitus and hypertension, contributing in the former case to the occurrence of hypotensive episodes and in the latter to the maintenance of the blood pressure elevation. In addition, baroreflex dysfunction is characteristic after myocardial infarction and carries a worse prognosis. The clinical relevance of a baroreflex dysfunction is supported also by studies showing that interventions that improve baroreflex sensitivity (BRS), such as physical training or β -adrenoceptor blockade, may also beneficially affect the patient's prognosis.

The above findings have led to great interest in the assessment of BRS in humans, both in the laboratory and the clinic. This article briefly addresses the role of the arterial baroreflex in cardiovascular physiology, its possible clinical relevance, and the methods most commonly employed for assessing its effectiveness in human cardiovascular regulation. Emphasis is placed on the exciting possibilities offered by modern approaches based on computer analysis of spontaneously occurring blood pressure and heart rate fluctuations.

Anatomy and Physiology

Intravascular pressure is continuously sensed by stretch receptors, located in the systemic and

pulmonary arteries and veins. The two main populations of receptors engaged in this task, known as baroreceptors, can be found at the carotid sinus and the aortic arch (i.e., in two key regions for continuous monitoring of blood pressure and thus of blood supply to vital organs, in particular to the brain). Other important baroreceptor populations involved in regulating perfusion pressure to vital organs are those located in the walls of cerebral and renal arteries, where they appear to play a major role in the local autoregulation. Arterial baroreceptors, in combination with the stretch receptors located in the cardiac walls and in the lungs (so-called cardiopulmonary receptors) also play a role in regulating the secretion of humoral substances involved in blood pressure and volume homeostasis (e.g., renin, vasopressin, catecholamines).

An increase in vascular or cardiac pressure determines an increase in arterial or cardiac transmural pressure, which represents the natural stimulus for stretch receptors located in the vascular or cardiac walls, and thus an increase in firing along their afferent fibers. The opposite occurs for a reduction in cardiac or vascular transmural pressure. The afferent impulses which follow baroreceptor stimulation by a blood pressure rise relay within the nucleus of the solitary tract in the brainstem. This is followed by inhibition of brainstem sympathetic centers and stimulation of brainstem parasympathetic centers. This baroreceptor reflex arc forms a negative feedback loop in which a rise in blood pressure results in the inhibition of central sympathetic outflow to the heart and peripheral circulation. This occurs through a sequential action on the intermediolateral cell column, preganglionic neurons, sympathetic ganglia, and, finally, on postganglionic sympathetic nerves directed to heart, arterioles, veins, and kidneys. The baroreflex negative feedback loop which responds to a rise in blood pressure also includes an increase in the activity of parasympathetic brain stem centers and in the efferent parasympathetic activity directed to the heart. The final result is a reflex reduction in blood pressure and heart rate, aimed at counteracting the initial increase in blood pressure. A brainstem noradrenergic pathway is also involved in this process, interacting with the nucleus of the solitary tract to participate in the suppression of sympathetic outflow. This noradrenergic inhibitory pathway is stimulated by centrally acting α -adrenoceptor agonists, such as clonidine, that may thus potentiate through this mechanism the baroreceptor-mediated vasodepressor response.

In the opposite sense, a fall in blood pressure is responsible for a reduction in baroreceptor transmural pressure and thus for a reduction in

baroreceptor afferent firing. This in turn diminishes central inhibition, resulting in an increase in sympathetic outflow and a reduction in vagal efferent activity and thus a reflex rise in blood pressure and heart rate aimed at counteracting the initial fall in blood pressure.

The arterial baroreflex loop, including the arterial baroreceptors, their afferent fibers, central integrating neurons, efferent fibers, and peripheral effector organs, represents the major regulatory mechanism involved in cardiovascular homeostasis and plays a pivotal role in buffering blood pressure fluctuations and in promoting heart rate variability. Moreover, data are available demonstrating that its derangement in a number of diseases, characterized by autonomic impairment, may not only contribute to the clinical manifestations of these pathological conditions, but may also have a prognostic relevance in increasing the risk of cardiovascular events. This makes the accurate assessment of baroreflex function in humans a key methodological issue.

Methods for Assessing Baroreflex Function

Laboratory Methods for Assessing Baroreflex Sensitivity

Several methods are available to assess the arterial baroreflex function in the laboratory. These techniques have been successfully used to clarify its physiological role in cardiovascular modulation, its alterations in disease, and also how this alteration can be modified by treatment. All of the methods require the application of an external stimulus on the subject under evaluation and offer a spot quantification of BRS obtained in standardized laboratory conditions.

A number of pioneering methods to assess BRS, including carotid sinus massage, electrical stimulation of carotid sinus nerves, anesthesia of carotid sinus nerves and vagi, and occlusion of common carotid arteries, are now only of historical interest. Other laboratory methods currently employed in this field include:

- The Valsalva maneuver (which, however, also triggers alterations in chemoreceptor and cardiopulmonary receptor activity, thus making heart rate responses poorly specific),
- Head-up tilting and lower body negative pressure application (which are also not specific because cardiopulmonary receptor deactivation, due to a reduction in venous return and central blood volume, and vestibular stimulation, in case of tilting, also contribute to the cardiovascular adjustments),
- The intravenous bolus injection of a small dose of a pressor or a depressor agent free from any major

direct effect on the heart (to increase or reduce systolic blood pressure (SBP) and reflexly lengthen or shorten, respectively, R-R interval; the slope of the regression line fitting the SBP and R-R interval changes is taken as a measure of BRS), and

- The use of a neck chamber device (which allows its inner air pressure to be increased or reduced in a graded and long-lasting fashion, thus resulting into graded, long-lasting, and quantifiable reductions and increases in carotid transmural pressure and, as a result, in the input stimulus to carotid baroreceptors).

The key advantage of the neck chamber method is that it allows not only heart rate but also blood pressure modulation by arterial baroreceptors to be specifically investigated (Figure 1). This goes with the disadvantage, however, that only carotid baroreceptor function is addressed and that the effect of carotid baroreceptor involvement is counteracted by the aortic baroreflex, which is deactivated during the blood pressure fall induced by carotid baroreceptor stimulation and stimulated during the blood pressure rise induced by the carotid baroreceptor deactivation.

Despite the useful information they provide on arterial baroreflex function in humans, all the above laboratory methods also carry a number of limitations, including the need of external artificial stimulation on the cardiovascular system, the limited reproducibility of the data so obtained, and the inability to characterize the dynamic features of neural cardiovascular reflex modulation in real-life conditions. This has stimulated the development of new techniques aimed at overcoming these problems.

Techniques for Assessing Spontaneous Baroreflex Modulation of Heart Rate

An important step forward in the investigation of the arterial baroreflex in humans is represented by techniques that analyze the sensitivity of spontaneous baroreflex control of heart rate, i.e., techniques based on the analysis of spontaneously occurring blood pressure and heart rate fluctuations. These techniques do not require any external intervention on the subject under evaluation, and can be used to assess BRS not only in standardized laboratory conditions, but also in daily life. From a methodological point of view, these methods require beat-to-beat monitoring of SBP coupled with an electrocardiogram signal to obtain a precise assessment of R-R interval–SBP relationships. If computer scanning of blood pressure signal is done at sufficiently high sampling frequency (≥ 100 Hz) and if the blood pressure waveform undergoes a parabolic interpolation of its peak, the heart interval can be estimated through the blood pressure signal only by quantifying

Figure 1 Blood pressure and heart rate effects of a 2-minute application of negative (a) and positive pneumatic pressure (b) within a neck chamber device. ABP, arterial blood pressure recorded through a catheter in the radial artery; $\int$ ABP, blood pressure values integrated every 10 s; bpm, beats per minute; HR, heart rate; MAP, mean arterial pressure; NCP, neck chamber pressure. Reproduced with permission from Ludbrook et al. (1977). pulse interval (i.e., the interval between consecutive systolic peaks), with a degree of accuracy comparable to that of R-R interval detection from an ECG tracing. A further simplification of the technical requirements for estimating the spontaneous baroreflex in humans is possible because continuous blood pressure recordings can be obtained through noninvasive devices with sufficient accuracy both at rest and in ambulatory conditions.

The sequence method The sequence method is a time-domain analysis, based on computer identification of spontaneously occurring sequences of three or more consecutive beats characterized by either progressive increases in SBP and reflex lengthening in heart interval (R-R interval or pulse interval), or by progressive reductions in SBP and reflex shortening in heart interval (Figure 2). Beat-to-beat changes should be greater than a minimum threshold (usually set at 1 mm Hg for SBP and 5 ms for heart interval) in order to form a sequence. Similarly to what is performed for the laboratory method based on the intravenous bolus injection of vasoactive drugs, the slope of the regression line between spontaneous SBP and heart interval changes is taken as an index of the sensitivity of arterial baroreflex modulation of heart rate (BRS). The experimental demonstration of the specificity of the sequence method (i.e., that R-R interval changes observed in each sequence in response to the spontaneous changes in SBP are actually dependent on the baroreflex) was obtained in conscious cats in which blood pressure and heart rate were continuously recorded for 3–4 h both before and after sino-aortic denervation. In intact animals,

thousands of sequences of either the hypertension/bradycardia or the hypotension/tachycardia type were identified, whereas after sino-aortic denervation the number of both sequences became negligible (Figure 3). The sequence technique can also provide additional pieces of information on the baroreflex function through two parameters: the occurrence rate of spontaneous sequences, usually quantified as number of sequences per hour; and the baroreflex effectiveness index (BEI). BEI is defined as the ratio between the number of sequences occurring in a given period of time, and the number of blood pressure ramps, i.e., progressive increases or progressive reductions of SBP of three or more beats. BEI may range between 0 (when the baroreflex does not generate any sequence to buffer blood pressure ramps) and 1 (when all SBP ramps belong to a hypertension/bradycardia or to a hypotension/tachycardia sequence).

Spectral methods A different approach for estimating the spontaneous BRS on the heart is based on frequency-domain analysis. This means that the dynamics of blood pressure and heart rate time series are analyzed by decomposing the overall variance (or power) as a function of the frequency of the individual oscillations contained in the signals (power spectrum).

α Coefficient Assessment of spontaneous BRS by the α coefficient technique is based on the computation of the power spectrum of SBP and R-R interval beat-to-beat series by either the fast Fourier transform (FFT) algorithm or through an autoregressive

Figure 2 Scheme illustrating the sequence method for assessment of spontaneous baroreflex sensitivity. Blood pressure is scanned in search of a sequence of beats in which a progressive increase of systolic blood pressure (SBP) is followed, after a lag of zero, one, or two beats, by a progressive lengthening of heart interval, measured as R-R interval or pulse interval (PI; hypertension/bradycardia sequence, as shown in the upper panel of the figure); or in which a progressive SBP decrease is followed after a similar lag by a progressive shortening of heart interval (hypotension/tachycardia sequence). Often it is required a minimal beat-to-beat SBP change of 1 mmHg, and a minimal heart interval change of 5 ms to identify a sequence, as in this example. The slope of the regression lines between SBP and PI or R-R interval values forming each sequence (lower panel) gives the estimate of baroreflex sensitivity.

modeling (Figure 4). The SBP and R-R interval spectra so obtained are then integrated obtaining a measure of power (in mm Hg² or ms²) over frequency regions where SBP and heart rate oscillations usually show a high level of linear correlation, which is assumed to be due to the baroreflex coupling. These regions are around 0.1 Hz (the so-called low-frequency [LF] band) and at the respiratory frequency, generally around 0.3 Hz (high-frequency [HF] band). The degree of linear coupling between oscillations in a

Figure 3 Number of hypertension/bradycardia (+pulse interval (PI)/+systolic blood pressure (SBP)) and hypotension/tachycardia (-PI/-SBP) sequences. Data are shown as average values ($\pm$ standard error of the mean (SE)) derived from the analysis of 3-h intra-arterial recordings for a group of 10 intact cats and for a group of 10 cats in which intra-arterial blood pressure was recorded 3 weeks after sino-aortic denervation (SAD). Asterisks refer to the statistical significance of the differences between the intact and the SAD conditions. Adapted with permission from Bertinieri et al. (1988). Evaluation of baroreceptor reflex by blood pressure monitoring in unanesthetized cats. *Hypertension* 12, 214–222. © 2002.

given frequency band is quantified by the coherence function (which can be considered as a type of linear correlation coefficient in the frequency domain). When the squared modulus of the coherence between SBP and R-R interval is sufficiently high, i.e., greater than 0.5, then the α coefficient is estimated as the root-squared ratio between the R-R interval power and the SBP power, in milliseconds per millimeter of mercury (ms/mm Hg). According to the frequency band considered for spectral integration, an α -LF or an α -HF coefficient is estimated.

Transfer function In part similar to the α coefficient, this method is based on the calculation of the SBP spectrum and of the cross-spectrum between SBP and R-R interval. The transfer function between the output, i.e., heart interval, and the input, i.e., SBP, is estimated as the ratio between the cross-spectrum and the SBP spectrum. The transfer function values in the LF or in the HF bands are taken as an estimate of BRS. If SBP and R-R interval are completely linearly correlated (coherence modulus equal to 1), α coefficient and transfer function estimates are identical. Otherwise, the transfer function method provides estimates lower than the α coefficients, because it tends to remove uncorrelated components from the output (heart interval).

Figure 4 Scheme illustrating baroreflex sensitivity assessment by calculation of the α -coefficient. From a few minutes long (typically, 10 min) beat-to-beat recording of systolic blood pressure (SBP) and R-R interval (RRI) time series (upper panel), SBP and RRI power spectra are derived and integrated over a low-frequency (LF) band between 0.07 Hz and 0.14 Hz (see figure) or over a high-frequency (HF) band around 0.3 Hz; the integral is the area under the curve. From the powers in the LF bands, RRI_{LF} and SBP_{LF} , the α -LF coefficient is obtained as the root square of the RRI_{LF}/SBP_{LF} ratio; the α -HF coefficient is similarly obtained from RRI_{HF} and SBP_{HF} . PSD, power spectral density.

Despite the methodological differences between time-domain and frequency-domain methods, average quantifications of BRS appear to be surprisingly similar. In either case, spontaneous BRS estimates so obtained are quantitatively different from (although closely related to) BRS values derived through the application of laboratory techniques. This emphasizes the complementary nature of the information on baroreflex function provided by laboratory and spontaneous methods, which focus on different aspects of arterial baroreflex modulation of heart rate.

Models

Physiological models Another approach for estimating the BRS is based on the mathematical modeling of the cardiovascular regulatory mechanisms. In this approach, each element of the model represents a specific component of the cardiovascular system.

The model identification is obtained by tuning the model coefficients in order to fit the experimental data. In particular, physiological models may allow to separately estimate a vagal and sympathetic BRS.

Black-box models Black-box models involve a different modeling strategy. It consists in describing individual elements of the cardiovascular system by means of mathematical equations whose coefficients do not have a direct physiological interpretation, but which can be efficiently estimated from the measured heart rate and blood pressure beat-to-beat series. Occasionally, these models also include respiratory signals. This class of models is generally based on a set of autoregressive and moving average equations reciprocally relating SBP and R-R interval beat-to-beat time series (ARMA models). The BRS can then be derived by a mathematical manipulation of the estimated model coefficients. This approach is particularly interesting because it may address aspects of the baroreflex function, in addition to BRS, that are difficult to investigate using experimental laboratory procedures, provided a suitable model is identified.

Other methods

Statistical link (Z-index) The statistical link (Z-index) method is based on the evaluation of the statistical dependence between blood pressure and heart interval as assessed by the Z-coefficient. The method determines the association between two probabilistic events, X and Y, calculating a statistical link coefficient, $Z(X,Y)$, which may range between -1 (when X and Y are mutually exclusive events) and $+1$ (when X is included within Y). Z is equal to 0 when X and Y are independent. Intermediate values between -1 and 0 quantify the partial exclusion of Y by X, while values between 0 and $+1$ quantify the partial dependence of Y on X. Z is estimated by counting the number of times that the X and Y events occurred, and the number of times that they occurred simultaneously, in a total of N observations. To quantify the statistical link between mean blood pressure and heart rate beat-to-beat values, the X and Y events are the occurrence of blood pressure and heart rate values within specific amplitude intervals. By choosing Q intervals for mean blood pressure and M for heart rate, $Z(X,Y)$ is defined over a grid of $Q \times M$ couples of (X,Y) events. The BRS can be estimated by the slope of the regression line in the X-Y plane fitting over-threshold Z values.

Cross-correlation (X-BRS) The cross-correlation (X-BRS) approach is based on the estimation of the cross-correlation between very short (10 s) segments of SBP and heart interval data. For any blood pressure

segment, the cross correlation is repeatedly estimated by considering sliding 10-s segments of heart interval with a time delay with respect to blood pressure up to 5 s. Segments showing the maximal correlation coefficient are selected and the slope of the regression line obtained from the corresponding SBP and heart interval values is the estimated BRS, provided that the probability of being a random regression is lower than 1%.

Clinical Value of Baroreflex Sensitivity

Spontaneous Baroreflex Sensitivity in Health and Disease

Data obtained by methods for assessing spontaneous BRS have provided a large body of information on daily baroreflex function in healthy subjects and on its derangement in disease. This information consists in the detailed evidence on the fast and marked changes in BRS associated with changes in behavioral conditions. Results provided by studies where these

methods were employed have clearly documented the high degree of variability which physiologically characterizes BRS in different conditions. The dynamic nature of the baroreflex assessment offered by techniques like the sequence method, as well as by other methods for spontaneous baroreflex analysis, has offered us the unique possibility to monitor both the slow and fast changes in baroreflex function, the most striking ones being those associated with the sleep-wake cycle. The typical patterns of spontaneous baroreflex modulation of heart rate over 24 h that characterize young and elderly subjects are shown in Figure 5. In addition to the occurrence of minute-to-minute variability, in young individuals BRS showed a clear-cut modulation between the day and night, displaying its lowest values during the daytime, under daily physical and emotional challenges, and its highest values during night sleep. In elderly subjects, 24-h BRS was not only on average smaller than in young individuals, but it also displayed a loss of the physiological day-night modulation, thus suggesting a multifold age-related impairment of baroreflex

Figure 5 Number of hypertension/bradycardia and hypotension/tachycardia sequences (left) and sequence regression coefficients (right). Data are shown as average hourly values ($\pm$ standard error of the mean (SE)) for a group of young and a group of elderly individuals. Adapted with permission from Parati et al. (1995). heart rate modulation. These techniques also allowed us to detect impairments of BRS in circumstances such as cigarette smoking, an impairment which escapes recognition when traditional laboratory methods are employed.

Assessment of spontaneous BRS also allowed quantification of changes in hypertensive subjects as compared to normotensive individuals; to quantify impairments occurring during sleep, like in patients with obstructive sleep apnea syndrome; and to study the striking baroreflex dysfunction typical of patients

with primary autonomic failure. Analysis of spontaneous BRS has also been performed in patients with diabetes with or without clinical and laboratory evidence of autonomic dysfunction, as documented by the classic Ewing tests. The results have shown that both time and frequency domain methods can identify impairments of baroreflex control of heart rate when traditional laboratory tests still yield normal responses. In addition, heart rate variability is only marginally reduced (Figure 6) emphasizing the superiority of these techniques as compared to

Figure 6 Time and frequency domain estimates of the spontaneous sensitivity of the baroreceptor-heart rate reflex in control healthy subjects (C) and in patients with diabetes without (D₀) or with (D₁) autonomic dysfunction at classical laboratory tests (*P < 0.05). SBP, systolic blood pressure. Reproduced with permission from Frattola et al. (1997). Time and frequency domain estimates of spontaneous baroreflex sensitivity provide early detection of autonomic dysfunction in diabetes mellitus. *Diabetologia* 40, 1470–1475. © 1997.

traditional laboratory procedures in the early detection of autonomic abnormalities that may carry a higher risk of morbidity and mortality. Because of the capability of these methods to provide continuous dynamic measures of BRS, they have been also proposed for the diagnosis of brain death on patients with severe brain injuries allowing the continuous monitoring of brainstem centers included in the baroreflex loop.

Prognostic Value of Baroreflex Sensitivity

The possible clinical relevance of a reduced BRS in patients with coronary artery disease has been suggested by both animal and human studies. The observation that a blunted reflex vagal modulation of the heart may be associated with a higher risk of major arrhythmias has stimulated a number of clinical studies aimed at assessing the possible link between BRS and patient's prognosis after acute myocardial infarction (AMI). Indeed, 2–7 days after an AMI, BRS was found to be markedly depressed by several studies. More consistent evidence on the clinical value of reduced BRS has been provided by a multicenter prospective study aimed at assessing the relative prognostic importance of several markers of neural autonomic cardiac modulation in patients after myocardial infarction (ATRAMI [Autonomic Tone and Reflexes After Myocardial Infarction] Trial). The results of this trial indicate that BRS is significantly related to patients' prognosis, even after accounting for the independent effect of other established prognostic markers such as the degree of heart rate variability and left ventricular function. In fact, BRS seems to represent a prognostic marker which does not provide redundant information as compared to heart rate variability. This is in line with the report that, in patients after AMI, subjects with and without a higher frequency of life-threatening cardiac arrhythmias, respectively, displayed a clear difference in BRS, but not a comparably clear-cut difference in heart rate variability. In spite of the above evidence, the real value of BRS in the evaluation of patients' prognosis after an AMI cannot yet be regarded as unequivocally clarified. Indeed, a clear-cut relationship between impairment of BRS on one side and the infarct size or the degree of left ventricular dysfunction on the other side was not found in a number of papers. The negative results on the relation between BRS and patients' prognosis obtained in some studies might also have depended, however, on the rather crude method which was employed to test the effectiveness of baroreceptor-heart rate control in these studies. This consisted in most instances in the evaluation of the reflex bradycardia which follows the increase in blood pressure

obtained by one or only a few bolus intravenous injections of phenylephrine.

The potential importance of BRS as a clinically relevant marker in cardiac patients has been further supported by a series of studies which showed that pharmacological and nonpharmacological interventions able to reduce sympathetic activity and to increase vagal activity and BRS may be protective against cardiac mortality and, in particular, sudden cardiac death. Administration of β -adrenoceptor blocking agents, which modulate cardiac sympathetic stimulation and increase BRS, was shown to improve morbidity and mortality in myocardial infarction patients even in the case of congestive heart failure. A similar mechanism might explain the beneficial prognostic effect in those patients who use angiotensin-converting enzyme (ACE) inhibitors and who exercise, interventions which have also been reported to increase BRS after AMI. Available data indicate that BRS may have a prognostic value also in two other pathological conditions, namely congestive heart failure and diabetes mellitus. In heart failure patients, the risk of death was significantly higher in patients with lower BRS as assessed by a neck chamber device, although the prognostic impact of a low BRS was no more significant when the influence of an increased sympathetic activity was simultaneously considered. This might depend on the inverse relationship that characterizes sympathetic and parasympathetic cardiovascular modulation, because evidence is available that deterioration of left ventricular function is associated with a decrease in parasympathetic tone. A reduced vagal tone thus may identify not only patients at high risk of sudden death, but also those at high risk of pump failure, both parameters being closely related to prognosis in heart failure. A reduced BRS has also been shown to correlate with an increased frequency of severe arrhythmias. Alternatively, a number of clinical studies have clearly shown the importance of a reduced vagal activity and of a deranged sympathetic activity on the prognosis of patients with diabetes mellitus. Indeed a number of patients with diabetes with clinically evident autonomic dysfunction die suddenly and unexpectedly, probably because of cardiac arrhythmias. Moreover, several studies suggest that even subclinical autonomic dysfunction may be predictive of future mortality in patients with diabetes mellitus. In conclusion, even if we have not yet clearly demonstrated that the prognosis of patients with myocardial infarction, heart failure, or diabetes, and the values of BRS are causally linked to each other, the available evidence is strongly in favor of such a possibility. Further progress in this field is likely to be supported by the recent development of more sensitive and

specific methods to assess spontaneous reflex cardiac autonomic modulation. Indeed, preliminary evidence is available that a reduced spontaneous BRS in patients after stroke is associated with increased mortality.

Conclusion

This article has summarized the role of the arterial baroreflex in human cardiovascular physiology and pathophysiology and the pros and cons of different methods for assessing BRS in humans. Laboratory methods have so far largely contributed to our present knowledge of arterial baroreflex function in humans. Modern techniques for spontaneous baroreflex analysis, however, have more recently provided us with a much deeper insight into the features of daily life baroreflex function as compared to what is offered by traditional laboratory tests. The recent evidence obtained in myocardial infarction patients, in patients with congestive heart failure, and in patients with diabetes through even the relatively crude estimates of BRS offered by laboratory tests has increased the interest in baroreflex analysis in humans. Whether the richer information provided by the new methods for assessing spontaneous BRS might further improve the prognostic evaluations of such patients, however, needs to be tested by large-scale longitudinal studies.

Types of Arthritis

Rheumatoid Arthritis

Does Stress Play a Role in Rheumatoid Arthritis?

Glossary

<i>Arthritis</i>	A group of disorders characterized by chronic pain and progressive impairment of joints and adjacent soft tissues.
<i>Autoimmunity</i>	An immune response directed at self tissues that can result in inappropriate tissue injury.
<i>Corticosteroids</i>	Natural or synthetic steroid hormones with potent anti-inflammatory actions.
<i>Cytokines</i>	Proteins produced by a variety of cells that mediate intercellular communication or other effector functions such as the generation or control of the inflammatory response.
<i>Hypothalamic-pituitary-adrenal (HPA) axis</i>	A complex set of direct influences and feedback interactions among the hypothalamus, pituitary and adrenal glands.
<i>Hypothalamus</i>	A part of the brain that contains cells that coordinate numerous body functions, including the activity of the stress response system.
<i>Inflammation</i>	A nonspecific response to injury that is intended to neutralize the cause of the injury and to orchestrate repair. It is characterized by heat, pain, redness, and swelling.
<i>Immunity</i>	A specific response to injury or potential injury that is intended to neutralize the cause or potential threat. Macrophages, lymphocytes, antibodies, and cytokines are important components of the immune response.
<i>Lymphocytes</i>	Cells that play key roles in mediating an immune response. There are two general types: B and T lymphocytes. B lymphocytes are primarily involved in producing antibodies; T cells are involved in cellular immune processes and in regulating the activity of other cell types, including B cells.

Macrophages

Major histocompatibility complex

Neuroendocrine-immune loop

Rheumatoid arthritis

Sympatho-adrenal axis

Synovitis

Synovium

Tumor necrosis factor (TNF)- α

Cells that play a key role in inflammatory processes. They engulf foreign materials and secrete an extensive array of biologically active substances such as cytokines. A group of genes located on human chromosome 6. Their name is derived from their role in triggering the rejection of transplanted tissues. They also have major roles in regulating the responsiveness of the immune system.

A theory emphasizing the bidirectional interactions between the brain and the endocrine and immune systems. The immune system stimulates and regulates the activity of the nervous and endocrine systems, and they, in turn, regulate the activity of immune system.

A specific type of arthritis that is characterized by progressive, symmetrical, destructive inflammation of multiple joints, particularly in the hands, wrists, and feet.

The adrenal medullary and autonomic sympathetic nervous systems; the major products produced are the catecholamines, epinephrine, and norepinephrine. The inflammation of the synovium; a major component of multiple types of arthritis.

A thin, delicate membrane that lines the cavity of joints. Its major function is to secrete substances, such as hyaluronic acid, that reduce the friction associated with joint movement.

A cytokine produced by activated macrophages that induces a variety of types of inflammatory injury.

Arthritis is the general term for a large, diverse group of musculoskeletal diseases characterized by chronic pain and progressive impairment of joints and surrounding soft tissues. These illnesses are very common and extremely costly to individuals, families, and society because they seriously impair work ability and decrease individual and household incomes. Affected individuals suffer from the inability to conduct the basic personal tasks, household tasks, and discretionary activities of living. For example, individuals with arthritis go out less frequently, spend less time with hobbies, and have much more difficulty earning a living or maintaining a household. Moreover, some forms of arthritis result in premature mortality in addition to severe disability.

Arthritis, particularly rheumatoid arthritis, is associated with an increased incidence of psychological distress and depression. Some of this distress is an intrinsic component of the disease process itself. In addition, the lack of independence and the inability to participate in various activities lead to frustration and feelings of helplessness. Not surprisingly, arthritis can strain marriages and family relationships.

Types of Arthritis

There are many forms of arthritis. Clinicians generally categorize arthritis into two major groups: monoarticular and polyarticular. Monoarticular disease is pain or swelling in a single joint, whereas polyarticular disease involves multiple joints. Monoarticular arthritis commonly results from joint infection or from gout or other types of crystal depositions in the joint. However, any of the diseases that produce multiple joint involvement can also present with a monoarticular pattern of joint involvement. Polyarticular joint disease is categorized into two subgroups: inflammatory and noninflammatory. For example, osteoarthritis is a very common noninflammatory polyarticular disease, whereas rheumatoid arthritis is a common inflammatory polyarticular disease. The inflammatory and noninflammatory joint diseases differ widely in their etiology and clinical findings. For example, the diseases may vary in regard to their mode of presentation (acute, subacute, or chronic), age at presentation, pattern of joint involvement, x-ray changes, and associated clinical laboratory abnormalities. More than 30 different forms of polyarticular arthritis have been defined. With regard to stress and arthritis, rheumatoid arthritis has been the focus of most research.

Rheumatoid Arthritis

Rheumatoid arthritis is the most prominent member of the polyarticular forms of inflammatory arthritis. Most patients with rheumatoid arthritis have a symmetric arthritis that involves the small joints of the hands and wrists. The disease may also affect the joints of the feet, ankles, knees, hips, elbows, shoulders, neck, and jaw. The lower spine is usually not affected. Prominent symptoms include stiffness upon awakening in the morning, fatigue, and severe joint tenderness and swelling. Later, joint deformity and limitation of motion become prominent. Patients may also develop skin nodules. In severe cases, other parts of the body may be involved, including the eyes, lungs, heart, and nervous system. A hallmark of the disease is an association with an

abnormal immunoglobulin called rheumatoid factor, which is present in the serum of approximately 80% of the patients.

Rheumatoid arthritis is considered a multifactorial autoimmune disease in that no single factor appears to explain its causation or pathogenesis; that is, multiple factors interact to produce the disease process. The disease is much more common in women than in men by approximately 3 or 4 to 1. The most likely period of onset for women is around menopause. Rheumatoid arthritis is uncommon in men younger than age 45, but its incidence approaches that of women in older men. Before menopause, it is common for women to develop rheumatoid arthritis within a year of pregnancy. Interestingly, the period around menopause and after pregnancy is associated with a decreased ability to produce corticosteroids in response to stressful stimuli. Conversely, rheumatoid arthritis rarely develops during a pregnancy, and patients with rheumatoid arthritis frequently improve significantly during a pregnancy. Pregnancy is associated with the production of high levels of the stress hormone cortisol, and many investigators believe that cortisol plays a major role in suppressing the expression of rheumatoid arthritis during pregnancy.

Genetic factors also play a role in determining susceptibility to and the severity of rheumatoid arthritis. The disease clusters in families and is associated with other autoimmune diseases. Current research indicates that multiple genes including genes associated with the major histocompatibility complex on chromosome 6 are involved in regulating susceptibility. The etiology of rheumatoid arthritis is not known with certainty. Many investigators suspect that an infectious agent is involved. Recent evidence supports the possibility that a parvovirus called B19 is involved, but much more investigation is required to confirm or refute this. A sustained autoimmune inflammatory process in the joints mediates the destruction of joints in rheumatoid arthritis. The joints are normally lined by a thin delicate membrane called the synovium. In rheumatoid arthritis, the lining layer becomes massively thickened and infiltrated by inflammatory cells, including macrophages and lymphocytes. The synovial tissue stromal cells also increase markedly in number. The hallmark of the disease, however, is the destructive erosion of bone and cartilage at the margins of the joint where the synovium attaches to bone. This erosive destruction leads to the loss of joint space and deformities of the joint. Current evidence indicates that the destructive process is driven by the sustained production of pro-inflammatory protein mediators called cytokines. $\text{TNF-}\alpha$ is considered to be one of the most important

cytokines in rheumatoid arthritis. Major investigative efforts are currently directed at neutralizing the effects of TNF- α in the joints. Interestingly, the anti-inflammatory corticosteroids are one of the most potent naturally occurring inhibitors of TNF- α production known. High levels of TNF- α production in rheumatoid arthritis has raised questions about the adequacy of corticosteroid production and the integrity of the neuroendocrine-immune stress loop in patients with rheumatoid arthritis.

Does Stress Play a Role in Rheumatoid Arthritis?

Studies of corticosteroids and rheumatoid arthritis are historically tightly linked. Cortisone was first isolated from adrenal tissue in the 1930s, but interest in corticosteroids rocketed when Hench and Kendall and colleagues described the dramatic anti-inflammatory actions of cortisone in patients with rheumatoid arthritis. Their discovery resulted in a Nobel Prize in 1950. Subsequently, it was realized that long-term high-dose therapy with cortisone resulted in devastating side effects. This development led to highly polarized views of the role of corticosteroids in rheumatoid arthritis. These controversies continue today.

Corticosteroids are prime examples of key stress hormones. They serve an essential role in a variety of systemic adaptive responses. We now call these adaptive responses the stress response. This response is necessary to preserve physiological integrity. Significantly, it is now known that components of the stress response system interconnect extensively with components of the immune and inflammatory response systems. This interaction is bidirectional. The production of inflammatory cytokines such as TNF- α normally triggers the production of cortisol as part of a systemic activation of the stress response and the HPA and sympathoadrenal axes; cortisol, in turn, suppresses the production of TNF- α and normally prevents the unchecked overproduction of the toxic inflammatory mediator. Thus, the feedback interconnections of the neuroendocrine-immune loop normally function to restrain the inflammatory system.

The importance of this feedback loop is exemplified by the LEW rat, an inbred strain that has a blunted or sluggish activation of the stress system in response to numerous stressors, including TNF- α . Interestingly, these rats are also highly susceptible to an inflammatory arthritis resembling rheumatoid arthritis and other forms of autoimmune disease, and these diseases are markedly attenuated if the rats are treated with physiological doses of corticosteroids

very early in the course of disease. The origin of the stress-system defect in these rats has not been completely defined, but it clearly involves the brain and the hypothalamus. The LEW rat contrasts strikingly with the F344 inbred rat, which has an overactive stress response system and is resistant to arthritis and a variety of other autoimmune diseases.

The observations in the LEW and F344 rats have led to extensive investigations, still ongoing, investigating the hypothesis that the stress response system is hypoactive in patients with rheumatoid arthritis. The data available to date suggest that the stress system is, in fact, underactive. Whether its underactivity is a primary or acquired pathogenic factor is not known. In any event, most investigators accept the view that stress and abnormalities of the stress system may play a role in rheumatoid arthritis.

Stress and Rheumatoid Arthritis

Stress and Osteoarthritis

A Special Case: Arthritis in Children

Glossary

<i>Adrenocorticotrophic hormone (ACTH)</i>	A hormone secreted by the pituitary that stimulates the adrenal gland to produce cortisol.
<i>Arthritis</i>	An inflammatory condition, primarily involving joints and surrounding tissue, that causes pain and may restrict mobility.
<i>Catecholamines</i>	Chemicals that serve as stress neurotransmitters in the nervous system and that are also secreted as hormones by the adrenal gland.
<i>Cortisol (hydrocortisone)</i>	A primary glucocorticoid that mobilizes energy for stress responses and serves as a potent anti-inflammatory and immunosuppressant.
<i>Epinephrine (adrenaline)</i>	One of the catecholamines responsible for the sympathetic (fight-or-flight) response.
<i>Flare</i>	Sharp but transient increases of inflammation and pain in some types of arthritis.
<i>Hypothalamic-pituitary-adrenal (HPA) axis</i>	A major neuroendocrine system involved in stress responses and responsible for production of catecholamines and cortisol.
<i>Pannus</i>	An abnormal growth of synovial tissue that is associated with joint destruction.
<i>Proinflammatory cytokines</i>	Intercellular immune messengers that increase inflammatory responses.
<i>Synovium</i>	A fluid-filled membrane that surrounds joints and provides joint protection, lubrication, and nutrition.

Definition

Arthritis is a term that covers over 100 inflammatory and degenerative joint conditions. The most common forms include osteoarthritis, rheumatoid arthritis, gout, ankylosing spondylitis, juvenile arthritis, psoriatic arthritis, and systemic lupus erythematosus. Despite having different etiologies, including infection, autoimmune pathology, and physical trauma, these

conditions are tied together by common characteristics of chronic pain and impairment in daily functioning. Stress–arthritis research has focused mainly on the two most common forms: rheumatoid arthritis (RA) and osteoarthritis (OA).

Stress and Rheumatoid Arthritis

RA affects approximately 3 million people in the United States and is three times more likely to occur in women than men. This autoimmune disorder is characterized by the inflammation of the synovium surrounding joints. The disease is typically symmetric, affecting the same joints on both sides of the body. Symptoms include swollen and/or tender joints as well as fatigue, low-grade fever, and general malaise. Many individuals with RA also experience episodic flares, in which symptoms are intensified. RA progresses from initial synovial inflammation to abnormal growth of the synovial tissue (pannus), which overgrows the joint area and breaks down surrounding bone and cartilage through the release of enzymes. RA can be severely disabling because of chronic pain and restricted joint flexibility.

Does Stress Exacerbate Rheumatoid Arthritis Symptoms?

Some evidence supports the view that stress may contribute to the onset of RA, but methodological challenges of retrospection diminish confidence in a number of these findings. A much stronger case has been made, however, for stress as being an aggravating factor in RA disease course. Minor stressors and daily hassles have, in particular, been linked to both self-reported pain and objective markers of inflammation. Both work stress and interpersonal stress predict increases of disease severity, and depression may further elevate stress-related inflammatory processes. Major acute stressors such as the sudden death of a spouse, on the other hand, may actually diminish the inflammatory response during the period of stress adaptation.

Biological support for stress–RA relations have focused mainly on proinflammatory cytokines, intercellular messengers responsible for triggering inflammatory immune responses. Many cytokines, including interleukin (IL)-1, IL-6, and tumor necrosis factor alpha (TNF- α) are stimulated by infection, physical trauma, and psychological stress. These stress-activated cytokines are also implicated in RA pathophysiology

to the extent that many pharmaceutical treatments are designed to suppress either the general immune system or specific cytokines. Biological response modifiers, the newest class of RA drugs, bind to proinflammatory cytokines and prevent their interaction with cell-surface receptors, thus inhibiting inflammatory immune responses.

In healthy individuals, the anti-inflammatory hormone cortisol (hydrocortisone) acts as an immunomodulator, suppressing both the production and activity of proinflammatory cytokines. Cortisol production may be induced through a stress response or triggered by increased levels of IL-6, serving as a modulating feedback loop. When endogenous cortisol levels are low, proinflammatory cytokine levels and disease activity are high. Daily circadian dips of cortisol in the early morning and late evening are associated with higher joint pain. Also, as cortisol levels diminish through late adulthood and old age, RA joint pain worsens. The recognition of hydrocortisone's anti-inflammatory properties led the wide use of externally administered glucocorticoids for managing RA symptoms.

Given that some stress hormones such as cortisol reduce proinflammatory cytokine activity, it may appear contradictory that stress increases pain in RA patients. It is important to note, however, that both pro- and anti-inflammatory agents are released during the stress response. Some stress hormones, such as prolactin, are proinflammatory.

The central pathophysiology of RA, then, may lie in the relative underactivity of anti-inflammatory agents compared with pro-inflammatory agents. This hypothesis is supported by observed dysregulations in the HPA axis. In RA, the HPA axis is probably underactive, leading to insufficient production of cortisol. Specifically, decreased cortisol secretion has been linked to diminished adrenal responsiveness to ACTH stimulation. RA patients may also exhibit abnormal responses to stress-induced catecholamines. In particular, it has been observed that externally administered epinephrine decreases cortisol in RA patients but not in healthy controls. If internal, stress-induced production of epinephrine similarly suppresses cortisol in RA patients, a proinflammatory state may be created, leading to the clinical observations of joint swelling and tenderness.

In addition to direct effects on peripheral sites of pain, stress may influence central processes involved in the affective responses to pain. Under periods of high stress and distress, RA symptoms and pain may be more salient. Conversely, positive emotion may buffer RA patients from the negative affective responses to pain, lowering stress reactivity and thus indirectly diminishing inflammatory processes.

Cognitive and Affective Factors in Rheumatoid Arthritis Stress–Pain Cycles

Given the exacerbating role of stress on RA symptoms, it is important to note that the disease itself may be a significant source of stress for afflicted individuals. In addition to pain, RA patients can suffer extensive physical limitations, which may lead to depressive symptoms and increased dependence on others. Activity limitations due to motion restriction and pain can affect every part of a person's life, impairing his or her ability to work, limiting recreational/social activities, and straining familial relationships. These physical and psychosocial stressors may further exacerbate pain and affect the disease course, potentially leading to a cycle of ever-increasing pain and stress. Not everyone is adversely affected by the disease, however, and many cognitive factors have been found to partially determine the impact of RA on a person's life. Premorbid depression, beliefs about the consequences of arthritis, and coping style all predict a more severe disease course. Resilient personality features and a strong social support network may sustain quality of life and forestall disability even among those with active disease. Positive emotion has also been associated with a reduction in proinflammatory cytokine activity and pain, suggesting that greater attention to emotion regulation may foster resilience.

The discovery of modulating cognitive factors has led to many psychological interventions for RA. Cognitive-behavioral interventions for arthritis management increase self-efficacy, reduce maladaptive coping styles, and decrease helplessness. By changing personal mastery, these therapies reduce negative interpretations of the disease and prevent an accumulation of stress that could further advance disease severity.

Stress and Osteoarthritis

OA is the most common form of arthritis, affecting nearly 30 million individuals in the United States. Symptoms of OA include joint pain, stiffness, and loss of mobility. Affected joints may include the knees, hips, lower back, neck, fingers, and the base of the thumb and big toe. Pain and stiffness is usually the most severe following long periods of inactivity, such as on waking in the morning. The disease is characterized by abnormalities in the cartilage, beginning first with a loss of elasticity. This initial stage is followed by the damage to surrounding bone, including the formation of growths and cysts. These malformations interfere with joint movement and cause pain. In later stages, the synovium may become

inflamed, leading to immune involvement and further cartilage damage and pain.

Although the pathophysiological profile of OA is very different from RA, many OA patients also suffer from considerable pain and physical limitation. OA sufferers complain of many daily stressors: pain, disability, and dependence on others. Fluctuations of OA pain are, like RA, influenced by daily stress. Unlike RA, there is little evidence that stress affects the disease processes.

Cognition and emotion regulation may serve as modulators between physical limitation/pain and consequent distress, however, and a number of factors can increase life satisfaction in those with OA. Greater self-efficacy and strong perceived social support both predict increased life satisfaction. Effective interventions often target these factors. Behavioral and cognitive-behavioral approaches may also help increase activities such as exercise that ease joint pain, increase mobility, and provide psychophysiological stress-buffering effects. Newer emotion-regulation interventions such as mindfulness meditation also show promise as a means of reducing the distress associated with pain episodes. These interventions may enhance psychological well-being, even for those with substantial disease.

A Special Case: Arthritis in Children

Individuals with juvenile arthritis (JA) suffer from complaints very similar to adult RA and OA. As with adult arthritis, there are associations between significant life stress and the development of JA, although a conclusive link cannot yet be drawn. Further, the same cognitive/coping factors seem to play important roles in determining the disease impact on life satisfaction.

Despite similarities, JA may be distinguished from adult arthritis by the added impact of the disease on social and psychological development. Children with JA most often complain of the disease hampering their performance in class, limiting their extracurricular activities, and limiting their activities with peers. Stress resulting from diminished social activities during critical development periods may have an impact on long-term psychological adjustment. Disease severity, however, is not always associated with psychological adjustment, suggesting that some variables play moderating roles. In particular, the child's attitude toward illness (positive or negative) can moderate the relationship between stress and adjustment, buffering the development of depression and strengthening the capacity for resilience. Major tasks for both parents and therapists, then, may be to teach alternative ways to interpret the disease, increase self-efficacy, and further

the development of emotional maturity. These strategies for disease management should be maintained even when the child needs support for the physical tasks in everyday life.

Stress as a Cause of Asthma

Stress Brings on Asthma Attacks

Stress Affects the Course of Asthma

Stress Reduction Improves Asthma Outcomes

Glossary

<i>Asthma</i>	Chronic inflammation of the airways, with reversible airway obstruction.
<i>Psycho-analysis</i>	School of thought in psychiatry that emphasizes the role of the unconscious in the etiology and course of psychological and somatic diseases.
<i>Psychology</i>	Study of the behavior of humans.
<i>Self-management</i>	An individual's ability to manage the symptoms, treatment, physical and psychological consequences, and lifestyle changes that are inherent in living with a chronic condition.

Asthma is a respiratory disease, defined as "... a chronic inflammatory disorder of the airways ... the chronic inflammation causes an associated increase in airway hyperresponsiveness that leads to recurrent episodes of wheezing, breathlessness, chest tightness, and coughing. These episodes are usually associated

with widespread but variable airflow obstruction that is often reversible either spontaneously or with treatment." (Clark, 2002). The hallmark of asthma is its reversibility: stimuli, such as stress, elicit episodes of shortness of breath that disappear, either spontaneously or following the administration of medication. Asthma is a highly prevalent disorder: some 10% of the population in industrialized societies is diagnosed with asthma. It now seems that the increase in asthma prevalence has reached its plateau.

Various stimuli lead to asthma attacks in susceptible persons. Stress is one of these stimuli. But there are also others, such as tobacco smoke, cat dander, aspirin, cold air, and exertion. It is the genetic and immunological factors that determine susceptibility to asthma in an individual. Asthma attacks translate into symptoms that lead to limitations in daily functioning, psychological morbidity, and negative social consequences.

Stress has been and still is conceptualized as potentially (1) contributing to the causes of asthma, (2) contributing to the inception of an asthma attack, (3) contributing to the clinical course of asthma, and (4) representing a target for therapeutic interventions in order to reduce the impact of asthma on the daily life of the affected patient. These four topics are discussed below.

Stress as a Cause of Asthma

Asthma is currently viewed as a multicausal disorder; the medical and scientific communities still do not have a perfect understanding of potential causal factors and their interrelations. Patients with asthma report

that stress is one of the major eliciting factors of asthma attacks, and that stress worsens the severity of their asthma attacks. Historically, these clinical observations have often informed past studies on whether stress is a causal factor in the etiology of asthma.

This research took place within a psychoanalytic and psychosomatic paradigm, en vogue in the first decades of the twentieth century. In this paradigm it was assumed that asthma was merely the somatic expression of an underlying source of stress: a psychological conflict within the patient or between the patient and a significant other. Asthma was conceived of as a symptom that symbolically expressed an anxiety neurosis: asthma nervosum could be traced back to the overhearing of the affected child of sexual activities between adults. In psychosomatic views on asthma, specific personality characteristics in combination with a specific interpersonal conflict or stress (centering on dependence vs. autonomy) were seen as the ultimate and main causes of asthma.

Empirical support for these views is not available, and therapeutic strategies following from these views (i.e., psychoanalytic therapy) failed to lead to improvements, with regard to either the disappearance of asthma altogether or reductions in the impact of asthma on the sufferer. However, some of the psychodynamic notions on asthma still seem to have survived. In a recent study on views of general practitioners (GPs) on asthma in various European countries, a GP remarked that "... as children these people very often have overprotective mothers (...) and when they've become adults they often live in circumstances where they do not want to share the air with other people." (Wahlström et al., 2001).

Research on the relation between stress or emotional arousal and changes in pulmonary function continues, but it remains unclear whether stress-induced airway obstruction really exists, let alone whether stress causes asthma. It seems safe to conclude that there is no evidence for the view that stress is an etiological factor in asthma.

Stress Brings on Asthma Attacks

Various stimuli and situations may elicit an attack of asthma in asthma patients. It is difficult for patients themselves, and for their partners and their physicians, to pinpoint exactly the stimulus or stimuli that caused or elicited a particular asthma attack. This, of course, complicates preventive or therapeutic measures. Quite frequently, patients attribute their asthma attacks to stress.

Experimental studies on stress and asthma assign short-term stressful tasks to be performed by healthy controls and people with asthma, in order to examine

their effects on various physiological processes, e.g., pulmonary function. In children with asthma, performing the stressful task of talking into a tape recorder for a 5-min period about a stressful or embarrassing incident led to increases in airway resistance of up to 20%, which is a clinically meaningful change. Observational studies in children and adults with asthma demonstrate that severely negative life events often increase the risk of the occurrence of asthma attacks over the coming few weeks.

Laboratory studies in a small sample of adult patients with asthma show that there is a close connection between the processes of inflammation in asthma and emotional factors, as measured with functional magnetic resonance imaging (fMRI). A recent study demonstrated that neural circuitry underlying stress and emotion can regulate inflammation, and peripheral inflammatory mediators can influence mood and cognition.

Stress Affects the Course of Asthma

As in almost any (chronic) illness, there are great variations in clinical outcome of asthma. Some patients are hardly affected by their asthma; in other patients, asthma appears to completely dominate their lives. A consistent research finding on these observations is that measures of objective severity of asthma are hardly associated with differences in outcome or course of asthma. The stress coping paradigm allows for the explanation of at least some of those differences.

Researchers in Denver, Colorado have developed the psycho-maintenance hypothesis, which pertains to psychological factors maintaining the course and consequences of a (chronic) physical disorder. The researchers examined relationships in hospitalized patients with asthma among objective indicators of asthma severity, psychological characteristics, and outcome measures. Length of hospitalization, frequency of rehospitalization, and severity of medication at discharge turned out not to be determined by objective asthma severity indicators, but by stress-related characteristics. Anxiety (panic-fear) as a personality characteristic, and as a transient state related to dyspnea perception, in combination with various attitudes toward asthma (e.g., optimism, stigma), however, did predict those outcome measures. These findings have been replicated in other settings and other countries.

In addition to stress and attitudes toward asthma, psychiatric morbidity is associated with outcome. Achieving a good control of one's asthma and adequate functional status often appears to be negatively influenced by higher levels of depression,

panic disorder, and social phobia. This relation again is hardly mediated by objective severity of asthma.

Symptom perception in asthma is also related to stress. Patients with higher levels of stress (negative affectivity) associate a wide range of nonspecific symptoms with their asthma, thereby altering the perception of the severity of asthma, which in turn influences their use of medication. These findings have great relevance for the topic discussed in the next paragraph: self-management skills for patients with asthma.

Stress Reduction Improves Asthma Outcomes

Teaching patients how to manage stress associated with asthma has a quite long history. Patients themselves indicate that when they become short of breath, they attempt to relax, which leads to subjective reductions in dyspnea. Behavioral scientists and medical professionals have examined the effects of relaxation training in patients with asthma to a great extent. However, the clinical wisdom of asthma patients has not been supported by empirical research. Relaxation therapies, biofeedback, and breathing retraining do not result in objective improvements in pulmonary function; neither do they affect clinical outcomes such as use of health-care services or medication.

Stress management training, however, appears to produce positive effects. Cognitive-behavioral stress management training leads to clinically meaningful and statistically significant improvements in children and adults with asthma. Cochrane Reviews reveal that medical care that encompasses teaching patients to perceive respiratory symptoms accurately, to respond to impending asthma attacks appropriately, and to cope well with the stress associated with dyspnea episodes and with asthma in daily social circumstances is associated with less disruption of daily activities, a better quality of life, and less use of health-care services.

Recently, two new areas of research pertaining to self-management of asthma have received much attention. The first is studying and examining the effects of expressive writing in adult patients with asthma. Patients have been encouraged to write about the most stressful event of their lives in the experimental condition, and about emotionally neutral topics in the control condition. Clinically meaningful improvements in pulmonary function were observed in the experimental condition. The second new area is research on illness representations, which pertains to studying the cognition of asthma patients of their respiratory condition and its treatment in relation to various outcome measures. Patients' own

ideas, objectively correct or not, turned out to be predictors of the clinical course of asthma. Future research will make clear to what extent these two new topics will be integrated into stress management programs for patients with asthma. Another challenge is to ensure that effective components of self-management training programs will be incorporated into guidelines for health-care providers and applied for the patient's benefit.

Glossary

<i>Adhesion/ aggregation</i>	The process by which active platelets connect with vessel walls and each other to form a thrombus.
<i>Angina</i>	Pain or pressure generally occurring in the chest or abdomen, sometimes radiating to the left arm, believed to be caused by ischemia of the myocardium. Equivalent symptoms may include dyspnea, dizziness, weakness, and palpitations.
<i>Angioplasty</i>	The introduction of a small balloon via a guidewire to an occluded segment of an artery followed by one or more inflations to reduce the narrowing caused by a blockage (also termed percutaneous transluminal coronary angioplasty, or PTCA).
<i>Arrhythmia</i>	Disorders of the normal sequencing of muscle contraction of the heart leading to inefficiency or, in some types, cessation of blood flow.

<i>Claudication</i>	Pain and weakness in the legs when walking caused by atherosclerosis of the arteries feeding the legs.
<i>Collagen fibrils</i>	The smallest structure of collagen (supportive tissue) formed by assembling molecules.
<i>Infarction</i>	Cessation of blood flow by thrombus formation, causing tissue death.
<i>Ischemia</i>	An imbalance of oxygen flow/availability and tissue need; usually due to obstruction by atherosclerosis with a superimposed thrombus.
<i>Perfusion</i>	The passage of a substance (e.g., oxygen) into tissues.
<i>Risk factors</i>	Behaviors or characteristics that have been found to be epidemiologically related to the development of a condition.
<i>Smooth muscle cells</i>	Cells found in the tunica media (middle layer) of arteries that proliferate with injury.
<i>Sudden cardiac death</i>	Death occurring within 1 h of symptom onset. Almost always attributable to atherosclerotic disease complicated by thrombus formation.
<i>Syndrome X</i>	The occurrence of angina-like symptoms in the absence of atherosclerotic disease or ischemia.
<i>Transient ischemic attack</i>	A brief period of dizziness, confusion, or cognitive dysfunction caused by ischemia of the brain.

Natural History

Atherosclerosis is an occlusive disease of the arterial walls that may occur at multiple sites in the body, but is most malignant when it threatens blood flow to critical organs such as the heart or brain. By itself,

atherosclerosis is of no clinical significance. But when atherosclerosis obstructs blood flow either transiently (ischemia) or long enough to kill tissue (infarction), it can cause transient dysfunction or permanent organ damage.

From a population standpoint, the most common clinical manifestation of atherosclerosis occurs when the heart is affected (angina, myocardial infarction, and/or sudden cardiac death). Atherosclerosis of major arteries feeding the brain can cause transient ischemic attack, multi-infarct dementia, or large, localized cerebrovascular accidents, while that of the legs can cause intermittent claudication and necrosis/gangrene and that of the kidney can cause renal dysfunction or failure.

While the initiation of atherosclerotic blockages, or plaques, is believed to occur throughout the life span, in at least some individuals initiation can occur as early as infancy in the form of fatty streaks. By the time a population cohort reaches late adolescence or early adulthood (e.g., young men killed in combat in Korea or Viet Nam), about one-third of young men display some degree of occlusion at postmortem, and a few percent have clinically significant occlusion (luminal blockages of 50% or greater in one of the major epicardial arteries of the heart, or any lesion of the left main segment). In middle age, most individuals have at least some low-level atherosclerotic disease. But women remain less at risk until menopause, when their risk begins to rise, matching men about 10 years later. However, even at advanced ages of 80 or greater, some people have coronary arteries entirely free of atherosclerosis.

In some individuals, at some sites, the myocardium has the ability to grow collateral arteries around occluded sites (perhaps provoked by exercise), which then serve as natural bypasses in the event of abrupt closure of the main trunk. Characteristics epidemiologically associated with the development or aggravation of atherosclerosis are referred to as risk factors. Age (older), sex (male), smoking (more), hypercholesterolemia, family history of early heart disease (early), hypertension, diabetes, and sedentariness are generally accepted risk factors for atherosclerosis.

Initiation of atherosclerosis occurs when the endothelium (a one-cell-thick lining of the arterial wall) is damaged. Multiple mechanisms have been suggested for this event and are not necessarily mutually exclusive. Mechanical strain, chemical insult, and infectious/inflammatory responses are thought to play a role. The cellular repair mechanisms result initially in a fatty streak. Recurrent insult to the site provokes migration of smooth muscle cells and collagen fibrils, resulting in a fibrous plaque. Continued insult and

attempted healing can produce an unstable plaque with a thin cap covering dead cells and a lipid-rich medium. Rupture of such a plaque, followed by platelet adhesion/aggregation and thus thrombus formation, is thought to be the sequence resulting in 85–90% of all myocardial infarctions. Vasomotor events (widespread constriction or localized spasm of arterial segments) may result in increased myocardial workload, plaque rupture, and/or superimposed thrombotic events, causing ischemia, which may trigger life-threatening arrhythmias for other patients.

The biochemical signals provoking each step of this process are still a matter of debate and investigation, but the validation of these theories is always to be found in intervention trials targeting the process but measuring the clinically important outcome. The role of platelet aggregation, for example, found its strongest validation in the powerful effect of antiplatelet substances (e.g., aspirin) in preventing cardiac events.

The significance of a plaque is determined primarily by the size of myocardium dependent upon its blood flow. Thus, plaques more proximal in the vascular tree or bush will produce greater muscle loss if abruptly rupturing and occluding. For 90% of patients (those who are left dominant), the left main coronary segment feeds both the left anterior descending and left circumflex arteries and thus carries higher mortality risk than more distal lesions with less territory at risk. Variants in coronary anatomy (e.g., right versus left dominance) determine the size of muscle affected.

Technical Limitations

The ability to study atherosclerosis is limited by the available technology. Firm measurement is most accurately obtained by postmortem examination of the arteries. Short of this, coronary angiography in living subjects is considered the gold standard. But even angiography has limitations:

- lesions that are low grade or tubular or longitudinal in shape are easily missed by the cardiologist's visual rating of the film;
- the cost and risk of the procedure means that the ethical justification for studying normals is difficult;
- asymptomatic coronary artery disease (CAD) patients will rarely show in cath labs;
- no distinction can be made between fibrous and unstable plaque (unless intravascular ultrasound is used); and
- one-third of cardiac patients whose first symptom is sudden death will not appear in angiographic samples.

Helical computerized tomography (CT) or magnetic resonance imaging (MRI) scanning has shown promise as a noninvasive means of imaging the larger proximal segments of the left anterior descending and left circumflex arteries, but provides less resolution of the right coronary artery. Indirect measures include the provocation of ischemia (by physical exertion, sympathomimetic agents, and/or mental stress) and subsequent measurement by electrocardiographic changes, or fixed (presumable permanently dead tissue) and reversible (transiently ischemic) myocardial wall motion changes (measured on echocardiograms or, more commonly, blood-pool-tagged radionuclide imaging) or radionuclide-tagged perfusion defects of the myocardial walls.

It should be emphasized that symptoms (dizziness, palpitations, dyspnea, or chest pain/pressure) either at rest or on provocation are only weakly linked with all presently available measures of ischemia, even in patients with documented coronary atherosclerosis. In patients with high risk factor loading, chest pain/pressure or dyspnea reliably provoked by exertion and relieved by rest or nitroglycerin may be the only symptom pattern indicative of ischemia. Crushing, substernal chest pain/pressure is considered classic for a myocardial infarction but only occurs in about 50% of such events.

Putative Mechanisms

The means by which psychosocial/emotional stress may cause or aggravate atherosclerosis are multiple. First, stress is clearly a major factor in diminished smoking cessation/abstinence and noncompliance with pill taking, dietary restrictions (cholesterol, sugar, or salt), and exercise. The impact of Zyban/Wellbutrin, a previously established antidepressant, on smoking cessation confirms this. Similar randomly-assigned, controlled clinical intervention trials have not yet been done for the other compliance mechanisms, but epidemiological evidence implicates emotional distress as a strong determinant.

Recent thinking implicates inflammation as a cause of plaque progression and instability. Inflammatory markers (e.g., C-reactive protein, interleukin-6) covary with depression, but we do not yet know if treatment of depression reduces such markers. To the extent that inflammation is caused by chronic, localized, smoldering infections (e.g., *Chlamydia pneumoniae*), depression-induced immunosuppression may enhance plaque growth/instability.

The best studied putative mechanism lies in acute or chronic emotional arousal provoking peripheral vasoconstriction (thus increasing myocardial

workload and oxygen demand) or vasospasm/constriction (and thus endothelial tearing or plaque rupture of susceptible lesions). It is clear that about one-half of patients with previously documented coronary atherosclerosis will demonstrate ischemia when mentally stressed (most reliably by verbal confrontations eliciting anger). Because the overwhelming majority of ischemic episodes on Holter exams occur in the absence of physical exertion (as indicated by heart rate and patient report), it is plausible that mental stress is a common cause of most ischemic episodes.

For the clinician, the question of mechanisms may be entirely moot since the benefits of diagnosis and treatment would accrue regardless of the mechanism, and the quality-of-life benefit alone justifies treatment.

Epidemiological Data

About two dozen studies have attempted to find cross-sectional associations between psychosocial/emotional stress and atherosclerotic severity in angiographic samples. The fatal flaw in these studies has been the failure to appreciate that the controls (i.e., patients whose results are normal or subclinical) used in these studies are physically symptomatic individuals with sufficient risk factor loadings to provoke concern. The occurrence of physical symptoms in the absence of disease implies that most of these control patients have high levels of somatized emotional distress (most notably panic disorder or depression, and referred to as atypical chest pain or syndrome X). Thus, the normals are not representative of a general or healthy population and are not appropriate as controls in studies intended to address etiology.

Only two studies have examined an angiographic sample while obtaining a healthy age/sex/socioeconomic status matched control group. Ketterer et al. recruited 176 males undergoing coronary catheterization with no prior history of revascularization and 56 males who had no history of atherosclerotic disease at any site. Traditional risk factors and multiple measures of psychosocial/emotional distress were quantified. In univariate analyses, several psychosocial measures (more depression as rated by a spouse or friend, more denial of depression as measured by discrepancies in spouse/friend minus patient ratings, more unprovoked nocturnal awakening, but lesser frequency of suicidal ideation) were found to be associated with atherosclerotic severity. This pattern of stigmatized symptoms (frequency of suicidal ideation) having a negative relationship with CAD severity, while spouse/friend-rated depression and a symptom with norms unknown to the layman (frequency of nocturnal awakening) having a positive

relationship with CAD severity suggests that denial is a major confound in measuring distress in this population. Indeed, the strongest correlate of CAD severity was denial of depression (measured by spouse/friend minus self-ratings on parallel versions of the same scale). This pattern unavoidably invalidates results obtained only from patient self-report measures of emotional distress, since the apparent accuracy of self-report data is not only weakened by denial, but also confounded with atherosclerotic disease severity. McDermott et al. have found anger-hostility to covary with disease severity in a similarly controlled study.

Angiographic study of atherosclerotic progression is limited by the ethical constraints imposed by an invasive procedure and costs. Several attempts to study coronary atherosclerotic progression exist in a patient population for whom clinical need (i.e., increased symptoms) existed. These reports found increased progression in patients with more type A behavior/hostility/overcommitment. Because we do not know the status of the arteries of patients in the original sample who did not undergo repeat angiography, nor do we know whether intertest angioplasty occurred, which might affect the second reading, it is doubtful that these studies provide much insight. However, repeat carotid ultrasonography (a noninvasive procedure not requiring clinical justification) also indicates progression in emotionally distressed patients.

Treatment Data

Ornish attempted an aggressive lifestyle modification program in 28 patients who underwent repeat angiography and 20 controls. Patients in the intervention group displayed modest (5%) regression of some plaques and were less likely to display progression than patients in a randomly assigned, usual care control group. Because the intervention had three prongs (vegetarian diet, daily exercise, and stress management), it is not possible to unambiguously ascribe the results to stress management alone. Ornish has not published data regarding hard clinical outcomes (myocardial infarction or death), although at least one report indicates decreased chest pain. Subsequent studies have found that lipid-lowering agents can also cause this sort of modest regression.

Now that noninvasive testing is possible (e.g., helical CT scans), it should be possible to do more and better epidemiological and treatment studies.

Definition and Overview

Aggravation, Complication, or Mimicking of ADHD

Symptoms by Stress

ADHD Symptoms as Stressors

Conclusion

Glossary¹

<i>Amphetamine</i>	Generic name for a stimulant medicine approved by the Food and Drug Administration (FDA) for treatment of attention-deficit/hyperactivity disorder (ADHD). It has two main brands: Adderall and Dexedrine. It is available in immediate-release tablets and extended-release encapsulated beads of different durations (Adderall XR and Dexedrine Spansule).
<i>Atomoxetine</i>	Generic name for a nonstimulant medicine approved by the FDA for treatment of ADHD. The brand name is Strattera. It is available only as an encapsulated powder.
<i>Clonidine</i>	A blood pressure medicine often used in the treatment of ADHD, especially with co-occurring tics or sleep problems. The brand name is Catapres. It is not approved by the FDA for treatment of ADHD but is commonly used, often with one of the FDA-approved drugs. It has been replaced somewhat by guanfacine, a similar drug with longer duration and less sedation.

ADHD with both six or more symptoms of inattentiveness and six or more symptoms of hyperactivity and impulsivity.

Pertaining to other disorders co-occurring with ADHD – i.e., in the same person at the same time

A form of disruptive behavior disorder typified by a repetitive and persistent pattern of behavior in which the basic rights of others or major age-appropriate societal norms and rules are violated. Referred to by the juvenile justice system as delinquency.

Antidepressant that has been shown effective for ADHD in controlled studies. The brand name is Norpramin. Used more in adults than children. Not FDA-approved for ADHD, but accepted by experts.

An array of psychiatric disorders marked by aggression, hostility, rule breaking, defiance of authority, and violation of social norms. The primary forms are oppositional defiant disorder (ODD) and conduct disorder (CD). Some authors include ADHD as a form of DBD.

A blood pressure medicine often used in ADHD, especially with tics. The brand name is Tenex. Although not approved by the FDA for this use, it is supported by a controlled study.

An old term for ADHD in the United States that is still used in Europe. Hyperkinetic literally means overactive.

Interference with normal function or performance.

Generic name for a stimulant medicine approved by the FDA for treatment of ADHD. It has several brands: Ritalin, Concerta, Metadate, and Methylin. It is available in immediate-release tablets and in several long-acting forms, including encapsulated beads of differing durations (Ritalin LA and Metadate CD) and an oral osmotic tablet (Concerta).

Steps that one can go through to see if experts would recognize a patient as having the disorder. If the patient meets all the operational criteria, one can be

	sure that clinicians anywhere who are familiar with the disorder would agree with the diagnosis.
<i>Oppositional defiant disorder (ODD)</i>	A form of disruptive behavior disorder typified by a pattern of negativistic, hostile, and defiant behavior.
<i>Pemoline</i>	Generic name for a stimulant medicine approved by the FDA for treatment of ADHD. The brand name is Cylert. It is not recommended as a first or second choice because of rare life-threatening liver damage.
<i>Posttraumatic stress disorder (PTSD)</i>	A form of anxiety disorder in which a person who was exposed to a traumatic event persistently re-experiences the event, avoids things associated with the event, and has persistent arousal that was not present before the trauma.

Definition and Overview

Attention-deficit/hyperactivity disorder (ADHD) is a common disorder of cognition and behavior originating in childhood. According to the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (DSM-IV), diagnosis requires, in addition to sufficient symptoms, that some of the symptoms must have caused impairment before age 7, some impairment is present in two or more settings, and there must be evidence of significant impairment in social, academic, or occupational functioning.

For the inattentive type, there must be six of the following nine symptoms:

1. Often failing to pay attention to details or making careless mistakes
2. Frequent difficulties sustaining attention
3. Often not seeming to listen
4. Often failing to follow instructions or failing to finish things
5. Frequent difficulty organizing
6. Often avoiding tasks that require sustained mental effort
7. Often losing necessary things for tasks
8. Frequent easy distraction
9. Frequent forgetfulness

For diagnosis of the hyperactive-impulsive type, six of the following nine symptoms are necessary:

1. Frequent fidgeting or squirming
2. Often leaving seat
3. Often running or climbing excessively
4. Frequent difficulty playing quietly
5. Often acting as if driven by a motor
6. Often talking excessively
7. Often blurting out answers before questions have been completed

8. Frequent difficulty awaiting turns
9. Often interrupting or intruding

For the combined type, the full-blown syndrome, there must be six symptoms from each cluster.

ADHD itself is not considered a stress disorder. However, it is related to stress in a number of ways. As with most disorders of health, both physical and mental, the symptoms can be aggravated by stress. Many of them can be mimicked by stress. Further, the symptoms of the disorder, especially if untreated, can cause stress both in the individual afflicted and in family members, especially parents, and in teachers, other caretakers, and peers. Later in life, residual symptoms of ADHD can stress spouses or significant others, employers, and co-workers. Finally, adults with residual ADHD can stress their children, whether or not the children also have ADHD. The following description assumes the untreated natural course of the full-blown disorder (combined type).

Aggravation, Complication, or Mimicking of ADHD Symptoms by Stress

Individuals with ADHD have a more tenuous functioning capacity than normal. They are more impulsive, less organized, less attentive to detail, less patient, more easily frustrated. They are also more likely to have additional problems, such as anxiety (about 30%), depression, or learning disorders (20–25%), which further compromise their functional abilities. They often have less adequate verbal memory or other perceptual, associative, or mnemonic ability. Some authorities believe that they are less easily rewarded by ordinary daily activities that normal people find sufficiently rewarding to maintain attention and interest, resulting in frequent boredom and lack of satisfaction. All this adds up to less coping ability. Consequently, the amount of stress needed to induce stress symptoms in these individuals is less than for other people. Since stress by itself can induce concentration and memory problems, it can add an extra increment of impairment to the attention and memory problems of ADHD. Similarly, stress-induced anxiety can add to the restlessness of ADHD, and impulse control often deteriorates further with stress.

Children who are suffering stress symptoms may appear to present with ADHD even if they do not have it. The hypervigilance, anxiety, restless sleep, and preoccupied inattention of posttraumatic stress disorder (PTSD) can mimic the distractibility, restlessness, and inattentiveness of ADHD. In a study of 117 children who appeared before a juvenile/family court secondary to experiencing significant child abuse and/or trauma, children with PTSD demonstrated concurrent ADHD, but not oppositional defiant disorder (ODD)/conduct disorder (CD). Indeed, children presenting

with ADHD symptoms should be routinely assessed for traumatic experiences. There may be a bidirectional association between child maltreatment and ADHD/ODD, with head trauma from abuse aggravating or even causing ADHD, and ADHD symptoms inviting abuse.

The anxiety, misbehavior, withdrawal, depression, preoccupation, easy frustration, and impaired performance of an adjustment disorder can also mimic the inattentiveness, misbehavior, impaired performance, and restlessness of ADHD. The agitation, withdrawal, impaired concentration, and irritability of stress-induced depression can mimic the restlessness, inattentiveness, and impulsiveness of ADHD. Indeed, the final DSM-IV criterion for diagnosing ADHD is that the symptoms are not better explained by another mental disorder.

ADHD Symptoms as Stressors

Untreated symptoms of ADHD stress the persons who have the disorder, their family – parents, siblings, spouse, and children – teachers, employers, and peers.

ADHD as a Stressor of the Person Afflicted

Children or adults with ADHD, though of normal or even superior intelligence, find it difficult to achieve at a level commensurate with their ability. They have to try harder to achieve the same results as peers of the same intelligence. The impulsiveness of the disorder may repeatedly get either children or adults into trouble before they realize what has happened.

For example, a child with inattention may have to struggle for an hour or two to complete the same homework that a peer of normal attentional focus can complete in a half hour. Even then, he or she may forget to turn it in on time and thus not receive full credit for it. Similarly, inattention can interfere with sports performance, a source of the greatest interest and pride for many children, especially boys, who outnumber girls with the disorder two or three to one. Inattentively missing the catch of an easy pop fly, making impulsive mistakes, or failing to hear or carry out the coach's instruction, thus incurring the contempt of peers and coach, or being chosen 18th when sides are chosen, can all stress one's self-esteem. Even at home, children with ADHD may find their achievement and behavior compared unfavorably with those of siblings of equal potential. They may be acutely aware of parental (or teacher) disappointment in their performance or behavior and conclude that they are not loved, at least not as much as siblings or classmates. Needing more prompting by teachers (and parents) for daily function, they may feel picked

on, nagged, and alienated from the usual sources of caregiver support. Thus, the developmental tasks of childhood, including acquisition of academic and social skills, basic skills of civilization, work habits, friendships, secure family relations, autonomous functioning, self-control, and self-confidence, are accomplished – if at all – at a more stressful price in the presence of ADHD.

In adolescence and young adulthood, the inattentiveness and impulsiveness of ADHD lead to poorer driving records than those of age mates (two to four times as many accidents). Parents are thus understandably reluctant to sign for a driving permit as early as the adolescent wishes, and are reluctant to allow use of the family car once a driver's license is obtained. Given the importance of a car for peer esteem and adolescent and young adult social life, this parental reluctance aggravates any family conflict, further cripples peer relations, and adds further increments of psychological stress. The impulsiveness and disorganization of the disorder also lead to a higher rate of teenage pregnancy in girls with ADHD and probably in girlfriends of boys with ADHD, not to mention greater exposure to sexually transmitted diseases. After all, precautions (including abstinence) require some reflection, organization, and impulse control. Thus, the interaction of ADHD with developmental issues of adolescence compound the ADHD-induced stresses from earlier childhood.

Adults with inattention become bored or frustrated with many jobs that others find tolerable or even interesting. They may wallow miserably in a lower-skilled job than their abilities deserve. Conversely, they may have an erratic work history, as their dissatisfaction and short attention span lead them to seek relief in job changes or even to impulsively quit without another job lined up. Employer dissatisfaction with poor attention to detail, restlessness, or failure to follow instructions may also lead to short tenures on many jobs. Thus, occupation, which should be one of the supports of self-esteem and satisfaction, may become an additional stressor economically and psychologically in the presence of ADHD. Similar patterns of frustration, boredom, restlessness, and difficulty sustaining commitment may dog social and intimate relationships of those with ADHD, who have lower rates of successful marriage. Failed love, separation, and divorce are well-documented stressors for anyone.

ADHD as a Stressor of Parents and Teachers

The constant activity, easy frustration, irritability, disorganization, tendency to lose things, and difficulty following instructions found in children with

ADHD can stress any adult attempting to manage their behavior, structure their activities, or teach them. It is particularly frustrating to teachers when they recognize that the child has the intellectual ability but is not doing the work. Many teachers agonize over the wasted potential, or even blame themselves for the child's poor performance. An unsuccessful intelligent pupil is stressful to the teacher's self-image. Erroneous conclusions that the child is lazy or obstinate can poison the teacher-pupil relationship and stress both teacher and child. This stress can possibly spill over into the teacher-parent relationship and affect all three parties.

Parents are stressed by similar disappointments and child performance difficulties at home, which is less intense than at school, but more consistent and enduring (every day, every year). Neglected chores, disorganized messiness, impulsive accidents, poor judgment, hectic overactivity and intrusiveness, conflicts with siblings, undone homework, calls from school, poor report cards, and other stresses are not what most parents anticipate at their child's birth. Such disappointments make it hard for parents to love (or at least hard to like) the child, leading to feeling guilty for being a rejecting parent. Criticisms of the child's behavior and the parents' child-rearing practices by well-meaning friends and relatives may add to the parents' feeling of failure. The child's impulsive destructiveness and accident proneness, as well as chronic need for professional services, round out the picture of a high-maintenance child who stresses the parents economically, physically, and psychologically.

Research has confirmed the profound impact of the problems of the ADHD child on the parents. In a well-controlled study of parent-child interactions, the placebo condition showed the mothers of boys with ADHD to be very directive, commanding, and negative with the child, with little positive interaction; when a dose of stimulant medicine was given to alleviate the child's ADHD symptoms, the same mothers became much friendlier and more respectful of the child, allowed the child more autonomy, and gave many fewer negative messages to the child. This demonstrated that the negative parental attitude often seen toward ADHD children is not part of the parents' personality, but a response to the child's problems. ADHD tends to bring out the worst in those around the afflicted person.

The negativity often spreads into the marital relationship as the frustrated parents disagree about how to handle the child's problems. For example, the father may blame the mother because he can get the child to behave for short times (sometimes by heavy-handed means) and the mother cannot get the child to behave during the much longer intervals she is

responsible for. The mother may feel that the father's disciplinary approach is abusive. Each may blame the other's genes. One parent may wish to medicate the child while the other objects to this. One parent may be enthusiastic about behavior modification but may find the system sabotaged by the other parent's failure to cooperate. In some cases one parent does not even recognize or admit there is a problem, while the other parent struggles with numerous complaints from school. One indicator of the marital stress engendered by a child with ADHD is the higher divorce rates reported for parents of such children. (This may be a partial cause as well as effect: divorce is stressful to children, and stress may nudge a subclinical case over the diagnostic threshold by aggravating otherwise mild symptoms.)

ADHD as a Stressor of Peers

Siblings, classmates, or teammates of children with ADHD are often unsung victims of the afflicted child's symptoms. The afflicted child's (proband's) needs for attention, supervision, and services tend to drain parent, teacher, and coach resources from siblings, classmates, and teammates. This relative neglect can sometimes be carried to the point of actual neglect, as all family efforts are focused on the impaired member. The whole family may have to forego outings that the proband cannot handle, or may cater to the proband, either out of pity or out of fear of impulsive tantrums. Older siblings' social life may be impacted by the need to monitor the proband, by embarrassment, or by the proband's intrusiveness. Younger siblings may be steamrolled by the proband's overactivity and inattentive thoughtlessness, or even be endangered by the proband's reckless impulsiveness.

Classmates or teammates may find their education, projects, activities, or games disrupted by the hyperactive child's impulsive intrusiveness, failure to wait a turn, failure to carry out an assigned part of the team's effort, need for excessive attention, failure to finish the activity, impulsive arguing, irritability, or other failure to be a good team player. It should be no surprise that children with ADHD typically fare poorly in peer sociometric ratings. Tragically, the hyperactive child's normal wish for friendships, implemented by clumsy, intrusive, impatient attempts to impose friendships, often only makes the situation worse. Thus, in the presence of ADHD, the normal need for peer relations stresses both the hyperactive child and available peers.

When ADHD persists into adulthood, the brunt of peer difficulties falls on the significant other, who may have to endure financial uncertainty as well as a disorganized lifestyle and interpersonal inconsistency and

unpredictability. Again, the high rate of failed marriages and other relationships stresses both the direct victim of ADHD and the indirect peer victims. Employers and co-workers also suffer some stress from the ADHD worker's inconsistent performance, restlessness, disruptiveness, failure to listen to or follow instructions, and failure to carry out assigned parts of a project. In some cases the need for the unpleasant task of firing the ADHD worker adds to the employer's stress. Even when the ADHD employee quits voluntarily, there is the stress of finding and training a replacement.

ADHD as Stressor of the Hyperactive Adult's Children

An important but as yet largely unstudied area is the stress on children of having parents with ADHD. Theoretically, parenting characterized by inattentiveness, inconsistency, impatience, impulsiveness, and disorganization should be stressful for any child. Since ADHD is highly heritable, an adult with ADHD has a good chance of having a child with ADHD. Because ADHD children have a special need for parental support and structure, we might expect that they would be especially vulnerable to the inattentive, unstructured disorganization of an ADHD parent. Conversely, what parenting skills the ADHD parent has will be challenged by the additional stress of a child with ADHD, in a vicious cycle. Thus both parent and child would be stressed by their mutual handicap.

ADHD Treatment as Stressor

Despite considerable evidence as to the effectiveness of pharmacotherapy in ADHD, there are considerable misgivings about the increasingly widespread use of medications, which may contribute further to the stresses of living with ADHD or with a child with ADHD. Parents (and children) are bombarded by media messages stating that medications are harmful or unsafe and can lead to abuse (of the medication or of street drugs), and that ADHD is a myth created by intolerant teachers and parents in an effort to place a pharmacologic leash on the child who only requires more discipline.

Any medication strong enough to treat ADHD is also strong enough to harm. One of the stresses of having ADHD or a child with ADHD is the worry about the long-term effect of medications, which is aggravated by media sensationalism. Sudden death due to medications is a recurring concern. In the 1980s this was reported in several patients taking desipramine, a tricyclic antidepressant known to cause cardiac slowing or blocking and that had demonstrated benefit in ADHD. In the 1990s the

combination of methylphenidate and clonidine (an antihypertensive) was reported to have contributed to the deaths of four children, all of whom had other complications such as preexisting cardiac disease (two cases), recent general anesthesia, or other medications. In 2005, Health Canada withdrew Adderall XR (an amphetamine stimulant) from the Canadian market, citing international safety information, including 14 reports of sudden deaths, heart-related deaths, and strokes in children and adults taking recommended doses of the medication. The Food and Drug Administration (FDA) in the United States reviewed the same data but had a very different interpretation and response than Health Canada. The FDA did not conclude that any immediate changes were needed in the approved use of this drug based upon its preliminary understanding of Health Canada's analyses of adverse event reports and the FDA's own knowledge and assessment of the reports received by the agency. However, because the stimulants are adrenergic agents, they can theoretically affect heart function, so a "black box" warning was added to the label as a safety precaution for the minority of patients who have a pre-existing cardiac abnormality. There is no evidence that the reported number of sudden deaths significantly exceeds those expected by chance, and Health Canada has reversed the ban, but the mere discussion is enough to worry many patients and parents.

Potential liver disease is another concern. By 1996, enough evidence had accumulated to confirm the risk of rare irreversible liver necrosis in association with pemoline, which was therefore demoted from a first-line drug to third-line. A recent report concerning a nonstimulant medication, atomoxetine, described liver enzyme elevations in two patients that resolved after the medication was discontinued. In a small, preliminary study, researchers found that after just 3 months, every one of a dozen children treated for ADHD with the drug methylphenidate experienced a threefold increase in levels of chromosome abnormalities – occurrences sometimes associated with increased risks of cancer and other adverse health effects. Even though no epidemiologic data have been found showing a higher rate of cancer in those who took methylphenidate (which has been on the market for 40 years), findings like this are still worrisome, adding to the natural stresses that the disorder brings.

Even nonmedical treatments can generate stress, especially if they are demanding or expensive, and thus stress family resources. For example, a systematic program of behavior modification requires considerable time and effort of the caregiver, who may feel that he or she has already given.

Conclusion

Untreated ADHD – and sometimes even treated ADHD – may be considered a stress generator, with a large ripple effect impacting practically all of society: the 35% of the population who have ADHD, their parents, siblings, teachers, classmates, teammates, mates, children, employers, co-workers, and even unknown other drivers. Thus, effective programs for preventing, curing, or controlling ADHD symptoms could ameliorate the fabric of stress throughout society.

How Can an Autoimmune Disease Be Initiated and How Can Stress Contribute to the Process?

If Stress Suppresses Immune Function, How Does Stress Predispose to the Development of Autoimmune Disease?

The Relationship of Stress to Specific Autoimmune Diseases
Summation

Glossary

Antibody

A protein that combines with the antigen that caused the antibody to be produced. Antibodies have specificity in that they combine most strongly with the particular antigen that stimulated their production. Antibodies are produced by a type of white blood cell called a B lymphocyte. Each B lymphocyte can only produce a single type of antibody, but the B lymphocyte produces thousands of that particular antibody molecule each second. Antibodies bind to antigens that are located outside of tissue cells.

Antigen

A substance that activates the immune system to produce a specific response that reacts against the antigen that activated the immune response. An antigen is usually something that is foreign to the body such as an infectious agent.

Autoimmunity

An immune reaction that is directed against an individual's own tissue. The immune reaction may damage tissue and cause disease.

Cytokine

One of numerous proteins made by a cell which can influence the activity of other cells. Cytokines bind to cytokine receptors on cells with different receptors binding different cytokines. Lymphocytes and antigen-presenting cells produce cytokines which, depending on the particular cytokine and the cell that it binds to, may either upregulate or downregulate the activity of other immune cells. Cytokines are also involved in the regulation of endocrine hormone production and contribute to the modulation of activity of the central nervous system.

Lymphocytes

White blood cells responsible for the immune response. Different types of lymphocytes originate from a common stem cell in the bone marrow. Lymphocytes that continue their maturation in the bone marrow become B lymphocytes, which function by producing antibody.

Tolerance

Lymphocytes that migrate from the bone marrow to the thymus gland for their maturation become T lymphocytes that function in cell mediated immunity, which is antibody independent.

The specific absence of an immune response to an antigen. This is usually an active process that is related to the deletion of antigen-reactive lymphocytes or a mechanism which suppress the ability of the lymphocytes to respond to antigen. Lymphocytes which have receptors for self-antigen (one's own tissue antigens) are eliminated by the tolerance mechanism(s).

How Can an Autoimmune Disease Be Initiated and How Can Stress Contribute to the Process?

Failure to Eliminate Autoreactive B Lymphocytes

The B lymphocytes are produced and mature in the bone marrow as part of the normal process of B cell maturation. Some B lymphocytes randomly develop immunoglobulin receptors that are reactive to self-antigens. Thus, they have the capability of releasing antibodies that react with self antigens. To prevent the development of autoimmune diseases, the autoreactive B lymphocytes must be eliminated before they can produce harmful reactions. The process of removal of autoreactive lymphocytes is called tolerance. Tolerance may be associated with actual death of the lymphocyte or its functional inactivation. The development of tolerance of newly formed autoreactive B lymphocytes must continue throughout life.

If the process of B cell tolerization were highly effective, no individuals would have autoreactive antibodies in their blood. However, nearly all normal individuals can be found to have low levels of antibodies directed to self-antigens. This suggests that the process of tolerization of newly developed B lymphocytes to self-antigens is not entirely effective.

As there is an epidemiological association of autoimmune disease with stress, it is possible that stress interferes with the tolerization of autoreactive B lymphocytes. Whether this is due to a stress-mediated decrease in the amount of circulating self-antigens which must be present in the marrow for B cell tolerance to develop, a decreased accessibility of self-antigens to the developing B lymphocytes in the marrow, a decreased susceptibility to tolerization of the autoreactive B lymphocytes, or other reasons is undetermined. For example, it is possible that stress hormones alter the kinetics of maturation of B lymphocytes so that there is a shorter window of

opportunity for B lymphocytes to become tolerant to self-antigens, alter blood flow to the bone marrow so that there is a decreased concentration of self-antigens present, or alter the release of self-antigens from tissue so that the concentration of these antigens is decreased in the blood.

Failure to Eliminate Autoreactive T Lymphocytes

The T lymphocytes arise in the bone marrow but mature in the thymus gland. Some of the maturing T lymphocytes have receptors on their surface membrane that will combine with self-antigen. It is in the thymus where the autoreactive T lymphocytes undergo the process of tolerization. Similar to autoreactive B lymphocytes, T cell tolerization may involve cell death or functional inactivation.

If all autoreactive T lymphocytes were eliminated in the thymus, there should be no autoimmune diseases. That autoimmune diseases occur indicates that the process is not totally efficient or that there are ways for T cells to escape from tolerance. If the hormonal response to stress alters mechanisms whereby T cell tolerance occurs, stress may increase the likelihood of an autoimmune disease occurring. It is possible that the hormonal response to stress alters the interactions between the cells that are responsible for the induction of tolerance of T lymphocytes. This may result in increased numbers of autoreactive T cells being present in the peripheral lymphoid tissues.

Alteration of Cell Regulation

In the spleen, lymph nodes, and blood, where many immune reactions are initiated, there are a variety of regulatory interactions which occur between cells of the lymphoid system. The mechanism of regulation is likely through the secretion of soluble factors by a particular type of cell that alters the activity of other cells. The hormonal response to stress may alter the function of the regulatory cells which then may predispose to an autoimmune response. Examples included are listed below.

1. Macrophages produce transforming growth factor- β (TGF- β), which inhibits proliferation of T and B lymphocytes. If stress hormones inhibit TGF- β production, activation of autoreactive T or B lymphocytes may be enhanced.

2. The CD4 Th2 lymphocytes produce the cytokines IL-4 and IL-10. These cytokines suppress CD4 Th1 lymphocyte function. Increased Th2 CD4 lymphocyte function, which is associated with a change in the balance between Th1 and Th2 function, has been associated with activation of latent viral infections. Th1 activity is important as it suppresses latent virus activation. An immune reaction against tissue cells

expressing viral antigens has been associated with the onset of autoimmune disease. Thus, stressor-induced alteration of the balance of immune function may contribute to the development of autoimmunity through the mechanism of latent virus activation.

3. The CD4 Th1 lymphocytes produce interferon- γ , which suppresses CD4 Th2 lymphocyte function. An increase of Th1 relative to Th2 activity has been associated with tissue damage in autoimmune disease. If the hormonal response to stress suppresses Th2 and increases Th1 CD4 lymphocyte function, an alteration of the course of autoimmune disease may occur.

There is a paucity of basic science studies relating to how an alteration of the balance between the various components of the immune system occurs when different concentrations of stress hormones are present. Such information is required before a determination can be made regarding the biological impact of stressor induced alterations of regulatory immune cell function.

Increased Susceptibility to Infection

Often, an acute stress or the experience of chronic stress decreases the function of the immune system. An increased susceptibility to upper respiratory viral infections and the reactivation of latent viral infections are the best documented indications of a biological effect of stressor-induced immune alterations. However, it is likely that resistance to any infectious agent is impaired by stress.

Infectious agents have been associated with the development of autoimmune diseases. Some infectious agents have antigenic sites that are identical to self-antigens. The presence of self and foreign antigenic sites on a single protein molecule frequently results in the breaking of tolerance to the self-antigen. For example, if infected with a bacteria that has an antigenic component on its surface that is identical to an antigen that is present on one's own tissues, tolerance can be broken. The antibody that is produced has the potential of altering the function of tissue or damaging tissue. Rheumatic fever is caused by this immune mechanism.

When a virus infects a tissue, an immune reaction to the virus kills the infected tissue cell. One of the mechanisms of cell killing is related to the release of enzymes from CD8 lymphocytes, neutrophils, and macrophages. The enzymes may degrade (denature) some of the molecules of self-antigen, resulting in a self-molecule that retains an antigenic site characteristic of the self-tissue and, in addition, has some antigenic sites that differ from self. When this molecule is processed by the cells of the immune system tolerance

is broken and an immune response to the self-antigenic determinant results.

If Stress Suppresses Immune Function, How Does Stress Predispose to the Development of Autoimmune Disease?

A logical concern relates to how stress, which is usually associated with a decrease in the function of the immune system, can be associated with diseases which are thought to be caused by increased immune activity. This can occur through alteration of the regulatory components of the immune system, as described above, or through an increased susceptibility to infectious diseases with a subsequent increased risk of an autoimmune response.

Obviously, the relationship between the effects of stress on altering the function of the immune system and the development of an autoimmune disease is complex. Further complications are related to different patients with the same disease having different etiologies to their disease. Eventually, clarification of the factors that contributed to the development of an autoimmune disease in a particular patient depends on identifying the immune pathway that was responsible for the disease in that patient. That allows a more precise characterization of the role of stress in the pathogenesis of autoimmune disease to be identified.

The Relationship of Stress to Specific Autoimmune Diseases

The following presents specific autoimmune diseases that have been shown to have an increased frequency of occurrence or which have an exacerbation at a time of stress. However, there are many unanswered questions in regard to the pathogenesis of autoimmune disease involving onset, remissions, and exacerbations. Many of the studies where stress in a person's life is associated with an autoimmune disease are flawed by the process itself. For example, if an individual who has been diagnosed with an autoimmune disease is asked to recall negative events in their life, that individual may try harder to recall such events or add meaning to events that would seem less important if the individual did not have an autoimmune disease. A person experiencing negative life events may see a physician more frequently just because they are not feeling well emotionally and may be more likely to be diagnosed with a disease at an early stage. It is also possible that early stages of disease that produce metabolic alterations (such as thyroid disease or diabetes) may have behavioral changes due to the altered concentration of endocrine

hormones in their blood which increase their likelihood of experiencing negative life events.

Psoriasis

Psoriasis is a skin disease that affects approximately 2% of the population. The involved areas of the skin are a pink color with white flaky scales. The skin lesions frequently undergo remissions and relapses. Psoriasis involves the infiltration of the skin with T lymphocytes and the production of disease-causing cytokines by the lymphocytes. An immune response to infectious agents in the skin may stimulate cytokine release. A hypothetical model can be constructed which supports the possibility that stress participates in the course of psoriasis by releasing neuropeptides from nerves which terminate in the skin. The neuropeptides, particularly substance P, may enhance the migration of lymphocytes into the skin which stimulate localized disease-enhancing cytokine release.

There are numerous published studies indicating that stress is associated with the exacerbation of symptoms in patients with psoriasis. A summary of the literature evaluating stress effects on the course of psoriasis supports the role of stress as a modulator of disease activity and suggests that the severity of the stressor may be associated with more severe disease. Additional studies have suggested that relaxation procedures which may produce a psychological relaxation (which would have an effect on the immune system if they decreased sympathetic nervous system activation) are capable of ameliorating the clinical appearance of disease in patients with psoriasis. However, there are many factors which make interpretation of the studies difficult. Usually the number of subjects is low and the stage of disease and the actual pathogenesis of the disease in the subjects may vary. Coping skills (including psychosocial support, physical fitness, optimism, sense of humor, and belief systems) which help to buffer the effects of stress on the immune system may vary. Even whether the subject experienced high levels of stress as a youth or the subject's mother experienced high levels of stress during pregnancy may influence an individual's response to stress.

Rheumatoid Arthritis (RA)

Rheumatoid arthritis is associated with a large accumulation of lymphocytes in the joint spaces. There is destruction of the joint spaces and considerable pain. Systemic manifestations include tendonitis, pericarditis, vasculitis, and subcutaneous nodules pleuritis. The disease frequently has a relapsing and remitting course.

It is usually assumed that the disease is produced by activation of the immune system to an antigen. As identical twins are often discordant for RA it is likely that there is an environmental (antigen) involved in the disease pathogenesis. However, there has not been identification of specific antigen(s) to which the immune response is directed.

If the disease is a response to an antigen the functional competency of the immune system and its modification by stress hormones could modify the disease course. If stress does alter the course of RA, it may be through dysregulation of the normal relationship of the various lymphocyte subpopulations to each other. Reports of the effect of stress on the clinical course of RA have been variable and do not provide an unambiguous understanding regarding whether stress alters the onset or course of disease.

Another approach to evaluating whether stress influences the course of disease in patients with RA is to evaluate the effect of stress reduction interventions. Psychological interventions have suggested that slight clinical improvement can be achieved in patients with RA. Thus, regardless of the difficulty in defining an immunologic etiology in RA or a definitive understanding of the pathogenesis of the disease, there is suggestive evidence for an interaction between stress and the disease process.

There are extensive studies which indicate that psychological intervention programs can decrease the pain perceived by patients with RA. Whether the pain reduction produces an alteration in the amount of opioid produced, both within the CNS and peripherally, and whether there is a subsequent change in immune system function which ameliorates the disease process has not been determined.

Recently diagnosed subjects with RA have a lower activation of the sympathetic nervous system following a mental challenge stress task than control subjects without RA. Those subjects with the greatest amount of pain had the lowest sympathetic activation. The lack of an intact stress response in RA subjects may indicate that the immune pathogenesis of RA differs from the immune pathogenesis of other autoimmune diseases or that RA is more likely to occur in subjects who have an impaired hormonal response to stress.

An impaired hypothalamic-pituitary-adrenal (HPA) axis hormonal response to stress may allow the immune system to become overactivated, promoting an autoimmune process. Indeed, experimental animals which have an increased susceptibility to the induction of arthritis have been found to have functional differences of their HPA axes (susceptible animals have a decreased production of corticosterone) in comparison to experimental animals which are resistant to the induction of arthritis. An abnormal HPA response to

immune and inflammatory stimuli has been reported in patients with RA.

Whether humans with RA have an altered response to stress because of modification of CNS function by cytokines or whether there is an innate difference within the CNS that modifies their response to stress has not been defined. However, subjects with another autoimmune disease, multiple sclerosis, have an intact response to the same psychological stressor that produced a diminished response in subjects with RA.

Graves' Thyroid Disease

Graves' hyperthyroidism is associated with weakness, nervousness, weight loss, fatigue, warm and sweaty skin, menstrual irregularities, heat sensitivity, protrusion of the eyes, and an enlarged thyroid gland. The pathogenesis is due to an antibody that binds to a receptor on thyroid epithelial cells that binds thyroid stimulating hormone (TSH). The thyroid stimulating antibody mimics the binding of TSH and stimulates the release of thyroid hormone. However, unlike TSH, which decreases in concentration as the concentration of thyroid hormone increases (reducing the releases of thyroid hormone), there is no inhibition of the physiologic effects of the thyroid stimulating antibody.

There are several studies which found that high levels of stress are more likely to occur in an individual who develops Graves' disease than in individuals who do not develop Graves'. These studies suggest that patients had more negative life events in the months preceding the clinical diagnosis of disease. However, not all studies support an association between prior stress and the onset of Graves'.

It is possible that if thyroid hormones are increased in concentration prior to the clinical diagnosis of disease, behavioral alterations are induced which either contribute to negative life events or the subject's awareness of negative life events. As thyroid hormone measurements are not made in the months preceding the appearance of clinical manifestation of Graves' disease, a possible influence of thyroid hormones on life events cannot be ruled out.

Multiple Sclerosis (MS)

Multiple sclerosis produces weakness, visual dysfunction, and paralysis. Multiple sclerosis lesions develop in the brain and the spinal cord where myelin surrounding nerve fibers is destroyed by lymphocytes and macrophages. There is an infiltrate of CD4 and CD8 lymphocytes, macrophages, and plasma cells. Nerve conduction is impaired. Identical twins have approximately a 50% concordance for MS,

indicating that both genetic and environmental factors are involved with the disease pathogenesis.

The exact pathogenesis of MS is uncertain, but there is considerable evidence suggesting participation of the immune system. This includes characteristic changes in the immunoglobulin content of spinal fluid, which suggests an immune reaction occurring within the CNS; the mitogenic responsive of lymphocytes from patients with MS to antigens derived from the CNS; the clinical response to immunosuppressive therapy; and the existence of an experimental model that is induced by immunization with myelin basic protein, an antigen found in myelin.

The studies of stress as a contributor to the etiology of MS are not definitive. They suffer from the faults of small sample size, heterogeneity of the extent and pathogenesis of disease, various stress buffering capabilities of subjects, and concomitant clinical depression having an effect on immune system function. Definition of the exact immune mechanism(s) which produce demyelination is also a hindrance, as without knowing which immune mechanisms are responsible for the tissue damage it is impossible to know which pathway is being altered by stress.

An increase of Th1 lymphocyte function would be compatible with an immune change that could increase the risk for the development of MS. Interestingly, cerebrospinal fluid (CSF) of patients with MS contains cytokines which promote CD4 Th1 lymphocyte activity. An indirect indication of predominant Th1 activity in MS patients is the paucity of IgE-mediated disease in MS patients, as Th1-derived cytokines suppress the Th2 cells that promote B lymphocytes to synthesize IgE. Stress has been found to increase the production of cytokines from Th1 lymphocytes while sparing alteration of cytokine production by Th2 lymphocytes.

There have been many studies which have looked at the association of stress with the clinical course of patients with MS. The studies found that MS patients had significantly more life stress prior to the onset of disease or disease exacerbation than did controls. The most common life events which were related to exacerbation were those involving financial or interpersonal concerns.

An interesting observation regarding stress and disease activity in MS was made during the Persian Gulf war. This study reported a decreased rate of exacerbations of MS during the war. This observation indicates that an intense psychological stressor can have a profound effect on suppressing immune system function and decrease disease activity. However, this is a unique situation that does not argue against less intense life-event stressors having an influence on the exacerbation of the clinical course of MS.

Overall, the clinical observations and the possible stressor-induced immune changes suggest that stress can alter the course of MS. Studies of stress intervention are needed to confirm or refute this hypothesis. Care will have to be directed to the clinical homogeneity of the patient population including HLA characteristics, social support and other buffering systems available to the patient, use by the patient of medications, and how strongly the patient believes in the potential effectiveness of the intervention therapy.

Insulin-Dependent Diabetes Mellitus (IDDM)

A frequent pathogenesis of IDDM is related to immune-mediated destruction of the insulin-producing β -islet cells. Antibodies to insulin and islet cell antigens are present prior to the clinical onset of disease and may indicate a destructive inflammatory process is occurring. Sensitized T lymphocytes that have a cytotoxic effect on islet cells are also present.

The disease is frequently preceded by a viral infection and may be initiated by an immune response to a virus that specifically infects β -islet cells. Indeed, virus has been isolated from the islets of newly diagnosed diabetic subjects and, when the virus is injected into mice, IDDM has occurred with an associated immune-mediated destruction of the β -islet cells. Active viral infection is suggested because of a rising antibody titer in the patient's serum to the isolated virus.

There are several reports associating life-event stressors with the onset of IDDM. Unlike diseases such as rheumatoid arthritis or multiple sclerosis, which have a relapsing and remitting course, IDDM does not remit. Therefore, studies showing an association of stress with alteration of clinical activity are nonexistent, but studies showing an association of stress with disease onset are numerous. Stressor-induced alterations of immune function may contribute to disease onset by (1) suppressing immune function and increasing susceptibility to viral infection and (2) altering the balance of regulatory lymphocyte populations which then allows an autoimmune response to occur.

Early reports linking stressors in an individual's life with an increased susceptibility to the development of IDDM were not rigorously controlled and presented small sample sizes. However, there are studies which suggest that there may be an association between stress and susceptibility to the onset of IDDM. These studies should be considered to be preliminary, as they have not addressed important questions.

Specifically, does stress increase the risk of IDDM onset in all individuals or only those who are HLA-DR3 and/or HLA-DR4 positive? If this association

only occurs in HLA-susceptible individuals, should the control group of individuals who do not have high levels of stress be restricted to HLA-DR 3- and/or HLA-DR-4-positive individuals?

The only way to control for genetic differences between subjects is to study identical twins. The concordance for IDDM in identical twins is approximately 50%. Environmental factors are usually designated as explaining the lack of 100% concordance. Environmental factors may include viruses, but may also include stress and the ability of a subject to cope with the stressor. A study conducted in identical twins both concordant and discordant for IDDM where factors such as stress, psychosocial support, physical fitness, belief systems, sense of humor, and being an optimist or a pessimist are considered would make a significant contribution to our understanding of the relationship between stress and susceptibility to autoimmune disease. If identical twins discordant for IDDM experience the same stressors, does the twin who develops IDDM have better coping skills?

Studies which have contributed to the suggestion of an association between stress and the onset of IDDM in children have found that severe emotional stress, usually associated with parental loss, especially occurring early in life, increased the risk for the subsequent development of IDDM.

Summation

Characterization of the potential interrelationship between stress and the development or exacerbation of an autoimmune disease requires knowledge of at least two parameters: (1) What components of the immune system are functionally altered by stress? and (2) How does alteration of the immune system initiate immune-mediated damage to self-tissue? Unfortunately, detailed information regarding each of the two questions is still lacking. However, there is abundant evidence from epidemiological studies that the experience of stress is associated with autoimmune disease onset or exacerbation. Continued studies of stressor-induced immune alteration and the mechanism of onset of autoimmune disease will help to clarify their relationship.

Summary

Glossary

- Brain stem** The portion of the brain connecting the cerebral hemispheres with the spinal cord, consisting of the midbrain, the pons, and the medulla.
- Endocrine** Pertaining to the secretory glands of the body, which release hormones that circulate in the blood to act on distant glands and target tissues to regulate their function.

Ganglion

A specialized collection of interconnected nerve cell bodies.

Homeostasis

A concept expressing the collective actions of the autonomic nervous system and endocrine system to maintain physiological systems within a range of optimal values consistent with the maintenance of life.

Hypothalamus

The collection of brain nuclei located below the thalamus that act to regulate the endocrine system and the autonomic nervous system to maintain homeostatic processes.

Limbic system

Brain structures of the cortex and basal ganglia that are involved with motivation and the emotions.

Neuro-transmitter

A chemical substance supporting communication across a synapse or neuro-effector junction.

Receptor

A complex protein molecule that is embedded within a cell membrane having chemical affinities for one or more neurotransmitters and that initiates a response by the cell.

In the course of daily life, we must rest or be active, obtain food and digest it, and, occasionally, cope with an exceptional challenge. At all times, during normal activity and during extreme stress, our brain coordinates the actions of our vital organs and our muscles to ensure our survival. The brain uses two systems to do this, the nervous system and the endocrine system. This article describes one branch of the nervous system, called the autonomic nervous system, which plays a central role in the stress response and in normal regulation.

Background

The peripheral nervous system has two branches: the somatic motor system, which controls voluntary movement, and the autonomic nervous system (ANS), which regulates the internal organs and the eyes. There are five main points to consider regarding the ANS and its role in the stress response: (1) the ANS, along with the endocrine system, regulates the vital organs and coordinates their functions; (2) the ANS is part of a layered set of controls over organ function, starting at the local organ and ending with the brain; (3) the ANS is controlled directly by two brain areas, the brain stem and hypothalamus, and indirectly by higher brain centers, including the prefrontal cortex; (4) during normal activity, the vital organs regulate themselves with little outside help, but during stress the ANS is needed to coordinate their actions; and (5) during psychological stress, the bodily responses we experience originate in higher brain centers that act on the brain stem and hypothalamus to cause changes in the body via the ANS.

Two historic figures have shaped our understanding of the functions of the ANS during stress: Claude Bernard (1813–1878), the French physiologist, who showed that living things must respond to changes in their external environment and in the internal environment (the blood and bodily fluids) to maintain proper cellular and organ function, and Walter Cannon (1871–1945), an American physiologist, who coined the term “homeostasis” to describe these processes of self-regulation. He showed that homeostasis was served primarily by actions of the ANS along with the endocrine system. Cannon demonstrated that the ANS reacts to emergencies in a pattern of widespread activation that he called the fight-or-flight response.

Autonomic Nervous System Compared to the Somatic Motor System

There are four points of comparison between the somatic motor nervous system and the ANS: (1) both of them are motor systems that regulate the activity of muscle fibers or secretory cells; (2) the somatic nervous system allows voluntary control over muscles, while the ANS automatically regulates the vital organs and related tissues without voluntary control; (3) somatic nerves always activate contraction of the somatic muscles, while ANS fibers will either activate or inhibit the vital organs; and (4) there are two anatomical differences between the somatic nervous system and the ANS ([Figure 1](#)). In the somatic nervous system, a nerve fiber goes directly from the central nervous system to a skeletal muscle. The ANS

(a) Somatic motor system

(b) Autonomic motor system

Figure 1 Neurons innervating the skeletal muscles (a) and the vital organs (b). (a) Skeletal motor nerves. Motor neurons that control the skeletal muscles travel from the motor portions of the cerebral cortex, down the spinal cord, and directly to individual muscle fiber bundles without synapsing with other neurons. (b) Autonomic nerves. The autonomic nervous system has two sets of neurons. Preganglionic neurons originate in the pons and medulla of the brain stem. They descend by way of the spinal cord and travel to autonomic ganglia, where they synapse with postganglionic neurons that travel to specific effector organs. There are three types of autonomic effectors: smooth muscle cells, secretory cells, and cardiac muscle. From Iversen, S., Iversen, L. and Saper, C. B. (2000). *The autonomic nervous system and the hypothalamus*. In: Kandel, E. R., Schwartz, J. J. & Jessel, J. H. (eds.) *Principles of neural science* (4th edn., pp. 960–981). New York: McGraw-Hill. Copyright The McGraw-Hill Companies, Inc. Used with permission.

is more complex, with two sets of nerve fibers: preganglionic fibers that travel from the central nervous system to a peripheral autonomic ganglion, where they synapse with postganglionic fibers that travel to a target organ.

Autonomic Nervous System Has Three Branches

The ANS has three branches: the sympathetic, parasympathetic, and enteric nervous systems. The two major branches, the sympathetic and parasympathetic, are diagrammed in [Figure 2](#).

Sympathetic Branch

Sympathetic preganglionic fibers exit from the middle, thoracic, and lumbar segments of the spinal

Figure 2 The sympathetic and parasympathetic branches of the autonomic nervous system. The sympathetic branch has preganglionic fibers that exit the spinal cord at the thoracic and lumbar vertebrae. These travel to the sympathetic chain ganglia, located near the spinal cord, or to the celiac or mesenteric ganglia of the gut. The sympathetic postganglionic fibers then exit their respective ganglia and travel to distant target organs. The parasympathetic preganglionic fibers exit the central nervous system either from the pons and medulla or from the sacral level of the spinal cord. The preganglionic fibers travel along several cranial nerves or the splanchnic nerve, and they travel some distance to their ganglia, located near or within the target organs. The postganglionic fibers then travel short distances to their target tissues. From Iversen, S., Iversen, L. and Saper, C. B. (2000). *The autonomic nervous system and the hypothalamus*. In: Kandel, E. R., Schwartz, J. J. & Jessel, J. H. (eds.) *Principles of neural science* (4th edn., pp. 960–981). New York: McGraw-Hill. Copyright The McGraw-Hill Companies, Inc. Used with permission.

cord. The sympathetic branch is so named because it operates in a coordinated fashion and in sympathy with the emotions. In general, the sympathetic branch regulates energy-using functions and is most active during states of fight or flight in order to maintain homeostasis in the face of external threats. It is also active during normal activities, but less so.

Parasympathetic Branch

In the parasympathetic branch, preganglionic fibers leave the central nervous system at points above

and below the sympathetic fibers, hence the name parasympathetic. The upper group of neurons exits the medulla by way of the cranial nerves. These exit the central nervous system directly from the pons and medulla and serve the head, neck, cardiovascular system, and gut. The lower group exits the sacral segments of the spinal column. Parasympathetic activity generally serves energy-conserving functions that Cannon called rest-or-digest. It is active in energy intake, such as feeding and digestion, and during reproductive functions, and it is most active during routine activities.

Enteric Branch

As the name implies, the enteric system pertains exclusively to the organs of digestion, including the pancreas, the gall bladder, and the gastrointestinal tract. Some consider the enteric nervous system to be a branch of the ANS, while others view it as part of the digestive system. All three branches of the ANS are active during normal activities, and they coordinate their actions to maintain homeostasis. However, the sympathetic nervous system predominates, and the other branches are inhibited during states of acute stress, such as periods of fight or flight, when resources must be devoted to the task of immediate survival.

Neurons and Neurotransmitters

There are two points of communication in the ANS. At a ganglion, preganglionic neurons synapse with postganglionic neurons. At a target organ, the postganglionic neuron forms a neuroeffector junction with a muscle cell or a secretory cell.

At both places, neurons communicate using specialized chemicals called neurotransmitters. These are released onto specialized receptors that activate either a postganglionic neuron or an effector cell. There are two ANS neurotransmitters, acetylcholine and norepinephrine (also called noradrenalin).

Preganglionic neurons always use acetylcholine to communicate to their postganglionic neurons. Postganglionic neurons use two primary neurotransmitters to act on their target tissues. In the parasympathetic branch, postganglionic fibers secrete acetylcholine at neuroeffector junctions located at target tissues. In addition, there are parasympathetic postganglionic fibers to the digestive tract that use the purine adenosine triphosphate as their transmitter. These purinergic fibers are involved in relaxation of the esophagus, stomach, and intestines. In the sympathetic branch of the ANS, postganglionic fibers secrete norepinephrine at their neuroeffector junctions. There are two exceptions to this rule. The sympathetic nervous system uses acetylcholine as a transmitter in the neuroeffectors of two tissues: the specialized sweat glands of the skin and the medulla of the adrenal gland.

Autonomic ganglia have an important feature. They are not simply relay stations; instead, they have small neurons that communicate directly between the larger pre- and postganglionic neurons. These small neurons secrete the neurotransmitter dopamine, which inhibits the main ganglionic neurons. The autonomic ganglia use this local inhibition to produce the first level of integrative control over the vital organs.

Anatomy of the Autonomic Nervous System

The brainstem contains several autonomic control nuclei that regulate the actions of the sympathetic and parasympathetic branches. Preganglionic fibers descend from these control centers to their autonomic ganglia, and postganglionic fibers travel to the target organs.

Sympathetic Division

The sympathetic division serves the eye, salivary glands, lungs, heart, liver, spleen, stomach, gut, kidney, genitalia, and all blood vessels except those of the brain. The actions of these sympathetic inputs are summarized in [Table 1](#) for each effector organ.

Sympathetic fibers exit from the spinal cord at thoracic levels 1–12 and lumbar levels 1–3. As shown in [Figure 2](#), there are two sets of sympathetic ganglia. The chain ganglia run parallel to the spinal column, and they are highly interconnected. A second, more distinct group includes the cervical and stellate ganglia, located in the neck, and the celiac, superior, and inferior mesenteric and renal ganglia found in the abdomen.

Sympathetic preganglionic fibers have four patterns of dispersal. Some preganglionic fibers enter the nearest ganglion and their postganglionic fibers exit at the same level of the ganglionic chain; other preganglionic fibers ascend the sympathetic chain ganglion to synapse in the cervical and stellate ganglia before they send postganglionic fibers to the eye, head, neck, mouth, and upper limbs and heart – the stellate ganglion serves the heart particularly. The blood vessels and skin of the lower body are served by postganglionic fibers that receive input from preganglionic fibers that descend from the lumbar and sacral ganglia; and, finally, certain preganglionic fibers pass directly through the chain ganglia without synapsing. They collect to form the three splanchnic nerves that pass through the diaphragm to enter the abdomen before arriving at the celiac, mesenteric, and renal ganglia.

A notable exception to this organization of sympathetic fibers is the innervation of the adrenal gland. In this case, sympathetic preganglionic fibers exit the spinal cord and travel directly to the adrenal medulla without synapsing at a ganglion.

The sympathetic nervous system is especially effective at promoting coordinated action of the bodily organs during states of stress. Its ganglia are close to the spinal cord and far from their target organs, and a single preganglionic fiber may send branches to several of the chain ganglia at different levels of

Table 1 Responses of Effector Organs to Autonomic Nerve Impulses^a

<i>Effector organs</i>	<i>Sympathetic receptors</i>	<i>Sympathetic impulses and responses</i>	<i>Parasympathetic impulses and responses</i>
Eye			
Radial muscle, iris	α	Contraction (pupil enlargement) ++	—
Sphincter muscle, iris		—	Contraction (pupil constriction) +++
Ciliary muscle	β_2	Relaxation for far vision +	Contraction or near vision +++
Heart			
SA node	β_1	Increase in heart rate ++	Decrease in heart rate; vagal arrest ++
Atria	β_1	Increase in contractility and conduction velocity ++	Decrease contractility, and (usually) increase in conduction velocity ++
AV node	β_1	Increase in automaticity and conduction velocity ++	Decrease in conduction velocity; AV block +++
Ventricles	β_1	Increase in contractility, conduction velocity, automaticity, and rate of idioventricular pacemakers +++	Slight decrease in contractility
Arterioles			
Coronary	α, β_2	Constriction +; dilation ++	Dilation +
Skin and mucosa	α	Constriction +++	Dilation
Skeletal muscle	α, β_2	Constriction ++	Dilation +
Cerebral	α	Constriction (slight)	Dilation
Pulmonary	α, β_2	Constriction +; dilation	Dilation
Abdominal viscera			
Kidney	α, β_2	Constriction +++; dilation +	—

	β_2	Amylase secretion +	—
Lacrimal glands		—	Secretion +++
Nasopharyngeal glands		—	Secretion ++
Pineal gland	β_2	Melatonin synthesis	—

^aReceptor types refer to receptors of the sympathetic nervous system. There are three types of sympathetic receptors: alpha (α), beta-1 (β_1), and beta-2 (β_2). α receptors are most sensitive to norepinephrine released from sympathetic nerve terminals. β_1 receptors are located only at the heart and in fat cells. These are sensitive to norepinephrine from sympathetic nerve terminals and to circulating epinephrine. β_2 receptors are mostly not innervated by sympathetic nerves. They are primarily sensitive to circulating epinephrine. The parasympathetic nervous system acts exclusively by secretion of acetylcholine on cholinergic receptors, regardless of the organ in question. The adrenal medulla is innervated by sympathetic preganglionic fibers that secrete acetylcholine. The sweat glands of the palms of the hands and soles of the feet are innervated by postganglionic sympathetic fibers that release acetylcholine. +, little action; ++, moderate effect; +++, large effect.

the spinal column. There is a ratio of 1 preganglionic fiber to 10 postganglionic fibers. This allows for coordinated activation of organs of the cardiovascular and pulmonary systems that are needed for coping with fight-or-flight situations. Epinephrine secreted by the adrenal medulla circulates throughout the body to act on noninnervated β receptors, further coordinating the organs sustaining fight or flight.

Parasympathetic Division

As shown in [Figure 2](#) and [Table 1](#), parasympathetic ganglia are located close to or within the organs they innervate. Preganglionic fibers arise from the brain stem and sacral region of the spinal cord. The eye, face, and mouth are served by cranial nerves III, VII, and IX. The cardiopulmonary and digestive systems are served by the vagus nerve (cranial nerve X), while the functions of excretion and control of reproductive organs are served by the splanchnic nerves.

The parasympathetic nervous system is designed to promote highly specific regulation of individual organs: (1) parasympathetic preganglionic fibers are long and travel to specific ganglia linked to specific organs; (2) postganglionic fibers are short and are sometimes found entirely within the innervated tissue; and (3) the ratio of pre- to postganglionic fibers is about 1:3, with one preganglionic fiber affecting only a single organ.

Autonomic Regulation of Specific Organs

[Figure 2](#) and [Table 1](#) summarize how the ANS regulates specific organs. The activity of each organ

involves interactions between the organ's intrinsic functioning and inputs from the ANS. In most cases, the sympathetic and parasympathetic branches of the ANS have opposite effects on the organs they innervate, and the balance of sympathetic to parasympathetic outflow determines the organ's final level of activity. This balance shifts constantly as the physiological and behavioral demands of the person change. During states of fight or flight, this balance is predominantly sympathetic in nature.

This regulatory interplay is illustrated in the activity of the heart. With no external controls, the heart beats automatically at a fixed rate of about 105–110 beats per minute. This rate is due to the heart's internal pacemakers, the atrioventricular and sinoatrial nodes. The pacemakers each have alternate phases of excitation and quiescence, and they interact to allow the heart to beat in a coordinated way. The heart's intrinsic force of contraction is determined by how well the ventricles fill with blood between beats and the resulting stretch on the walls of the ventricles. Greater wall tension results in a more effective contraction, with more blood being pumped on the next beat. These intrinsic mechanisms are entirely adequate to sustain life if conditions are constant and no threats to homeostasis are present.

The two branches of the ANS are active at all times, and they coordinate their actions to regulate the heart during all levels of demand on the circulation. During most normal behavioral states, the predominant ANS influence on the heart is through the parasympathetic branch. This branch acts on the heart by way of the vagus nerve, whose firing serves to lower the heart's

rate and force of contraction. The heart's intrinsic rhythm is normally regulated by this parasympathetic input. Up to and including moderate demands on the circulation, the parasympathetic branch can allow the heart to pump more blood simply by firing less often and allowing the heart to increase its rate up to its intrinsic rate.

At times of increased demand, the ANS may cause the heart to change its rate and force of contraction, and it may have to coordinate these changes with changes in the state of the peripheral blood vessels. A rapid change in circulatory demand occurs, for example, when a person suddenly rises from a chair, at which time there is a danger of blood pooling in the legs, causing a loss of circulation to the brain. This danger is averted by a rapid increase in firing by the sympathetic nerves that increase the rate and force of the heart's contractions and also increase the constrictive force of the blood vessels of the lower extremities. During more severe and sustained demands, such as intense physical exercise, the parasympathetic outflow to the heart is almost absent, and the sympathetic influence increases toward a maximum. In addition, endocrine input to the heart by circulating epinephrine greatly augments the heart's contractions. These three influences can cause a sevenfold increase in the volume of blood the heart pumps each minute. In a trained athlete, such increases in circulation can be sustained for hours.

These examples illustrate that the heart can function without outside control if no response is called for. However, the ANS must provide external control to meet rapid or sustained demands on the circulation and to help the heart operate in concert with the blood vessels. Circulating hormones, such as epinephrine, compliment the actions of the ANS to achieve the necessary level and coordination of cardiovascular response during stress. Similar arguments apply to the ANS regulation of other organ systems.

Local Regulation of Autonomic Function

Since ANS controls, especially sympathetic activity, are more or less nonspecific for each organ, there has been considerable interest in local mechanisms that can fine-tune organ function. The previous section illustrated the interplay of intrinsic and extrinsic regulation of the heart. There is still another level of fine-tuning of ANS actions at a given tissue. In all organs, ANS input is regulated by locally released biochemicals classified as peptides, neuromodulators, or metabolites. These act by several mechanisms at either the smooth muscle or the autonomic-neuroeffector junction to modify ANS activity or its effectiveness.

An example of the action of such local modulators is seen in the regulation of blood flow. Blood flow into the tissues is regulated by sympathetic activity at local blood vessels in concert with local metabolic demands. To regulate the level of tonus at the blood vessel wall, sympathetic nerves release norepinephrine at the sympathetic neuroeffector junction, causing contraction of networks of smooth muscle cells, increasing constriction of the blood vessel. This constrictive force can reduce blood flow into a local volume of tissue. If this were the only influence, the cardiovascular system would not adequately regulate blood flow according to the specific needs of local tissues. However, this constrictive force is balanced by local chemical substances that act on the blood vessel wall in relation to the activity of the local tissues and their consequent need for increased blood flow. Metabolites produced by cellular activity can act locally on smooth muscle cells to regulate their activity. For example, carbon dioxide produced by tissue metabolism leads to local production of nitric oxide, and nitric oxide causes relaxation of vascular smooth muscle cells. This results in the relaxation of blood vessels, allowing improved blood flow to a local volume of tissue. In this process of local autoregulation, exercising muscles produce more carbon dioxide when they are working harder, causing greater relaxation in the local resistance vessels and increasing the local blood supply. Neuromodulators can act on the sympathetic nerves themselves to regulate their actions on smooth muscle cells. In the sympathetic nerves, adenosine diphosphate is released along with norepinephrine at the adrenergic nerve terminal. This adenosine diphosphate is rapidly metabolized to adenosine, which then acts on adenosine receptors located on local sympathetic nerve terminals to decrease the release of norepinephrine. The greater the level of sympathetic outflow, the greater the production of adenosine, and the greater the modulation of neurotransmitter release. In the case of the blood vessel wall, autoregulation and neuromodulation work together to balance the effects of sympathetic activation and constrictor tonus, allowing blood flow to be controlled according to local tissues needs. Similar processes occur in the heart muscle.

The balance of intrinsic regulation, ANS inputs, and local regulation occurs in all tissues. This interaction fine-tunes organ function to maintain homeostasis.

Physical and Psychological Stress

Physical and psychological stress result from very different causes, but they both influence the body

by way of the ANS. The earlier example of a person arising from a seated position illustrates a physical challenge to homeostasis that results in a response by the ANS to maintain blood flow to the brain. This ANS response is coordinated by reflex mechanisms in the large blood vessels and brain stem that sense an impending drop in blood pressure and orchestrate the shift toward a sympathetically dominated state until blood flow is normalized. Such ANS responses are referred to as bottom-up because their source is in the body, involving some physical threat to homeostasis.

Psychological stress has a different origin. Our bodies can undergo significant changes in activity when we are anxious, ruminating about past failures, or in an acute state of fear. However, these changes originate in the highest centers in the brain, including the prefrontal cortex and limbic system. These ruminations result in signals to the hypothalamus and brain stem that can cause changes in the state of the body through the ANS and endocrine systems. These brain mechanisms therefore exert a top-down effect on the state of the body. In this manner, psychological stimuli can act as stressors in themselves. These can alter the usual homeostatic balance of the body.

Summary

The ANS and the endocrine systems are the brain's two primary pathways for regulating the vital organs. The ANS innervates all tissues outside of the central nervous system. It regulates contraction of smooth muscle cells and cardiac muscle cells and output by secretory cells. Changes in the internal or external environment of the body are normally countered by the ANS, which serves to maintain homeostasis. The ANS itself is controlled by the brain stem and

hypothalamus. The highest level of control is provided by the brain's limbic system and cerebral cortex. During times of emotional distress, influences descending from these higher centers alter the activity of the hypothalamus and brain stem. These psychologically induced influences can change the activity of the ANS to alter the state of the body and temporarily alter the homeostatic balance.

Glossary

Autoimmunity The activity of the immune system targeted against body's own (self) components. In a healthy situation, the immune system protects the body against invading pathogens such as bacteria and viruses. However, as a result of a series of orchestrated events involving genetic and environmental factors, there is a break in self-tolerance and the immune system starts attacking the body's own cellular components, which, if uncontrolled, can lead to pathological damage and autoimmune disease.

Autoimmune diseases Diseases caused by autoimmunity; can involve multiple body tissues (systemic) or be restricted to a particular tissue (organ-specific). Examples are multiple sclerosis, rheumatoid arthritis, systemic lupus erythematosus, and thyroiditis.

Heat-shock proteins (Hsps) A group of intracellular proteins whose expression is induced by a variety of environmental stresses such as heat, cold,

Hypothalamic-pituitary-adrenal (HPA) axis

Oxidative stress

Reactive oxygen species (ROS)

Tolerance/self-tolerance

oxygen deprivation, and other physical and chemical stressors; also called stress proteins. Under normal healthy conditions, Hsps act like chaperones, binding to other cellular proteins and preserving their shape and function, and also participating in their transport within and outside the cell. Under stressful conditions, Hsps protect other cellular proteins from denaturation. Hsps also participate in the display on the cell surface of peptides derived from other proteins for presentation by the MHC molecules to cells of the immune system. The communication and interplay among the three endocrine tissues via specific chemical mediators secreted by these tissues. The hypothalamus secretes a hormone named corticotropin releasing hormone (CRH) in response to stress. CRH acts on the pituitary gland cells that secrete adrenocorticotrophic hormone (ACTH), which in turn acts on the adrenal gland, leading to the secretion of adrenal stress hormones (e.g., cortisol). The adrenal hormones initiate various metabolic events to counter the effect of stress, and they also provide negative regulatory feedback signals to the hypothalamus and the pituitary gland to regulate the secretion of CRH and ACTH. An altered HPA axis activity has been implicated in many diseases, including some autoimmune diseases.

A state of relative excess of reactive oxygen species (ROS) such as oxygen ions, free radicals, and peroxide within the cell. Oxidative stress is linked to disease processes including aging, atherosclerosis, and Alzheimer's disease.

Oxygen species such as oxygen ions, free radicals, and peroxide within the cell. The activity of ROS normally produced during various metabolic processes is controlled by naturally occurring antioxidants; however, in excess ROS are harmful, leading to damage to cellular components such as lipids, DNA, and proteins. Thus, ROS are involved in normal cellular functions, but they also can induce tissue damage leading to mutagenesis and cell death.

A state of immunological unresponsiveness to a self-antigen without compromising the ability of the immune system to

immune tolerance

respond to a foreign antigen. Tolerance is effected by the deletion or inactivation of potentially self-reactive T and B cells during their development in the thymus and bone marrow, respectively (central tolerance) as well as by the control of the activity of self-reactive T and B cells in the periphery (peripheral tolerance) via a variety of mechanisms. A state of tolerance against foreign antigens can also be achieved using the appropriate experimental conditions.

Self-Tolerance Is Executed through the Deletion and Regulation of Autoreactive Lymphocytes

Immunological tolerance is the basic property of the immune system that provides for self/nonself-discrimination so that the immune system can protect the host from external pathogens without reacting against itself. Central tolerance is achieved by the clonal deletion of self-reactive lymphocytes expressing receptors with high avidity for self-ligands. Autoreactive lymphocytes that have escaped negative selection in the central lymphoid organs (the thymus and the bone marrow) are present in the peripheral repertoire, but are kept under control by multiple diverse peripheral tolerance mechanisms. These include anergy (functional inactivation) induction in lymphocytes that recognize self-ligands (first signal) in the absence of appropriate costimulation (second signal) on nonprofessional antigen-presenting cells (APCs), activation-induced cell death (AICD), cytokine-mediated regulation and various types of regulatory cells. The failure of tolerogenic mechanisms either within the central lymphoid organs or in the periphery permits the activation and expansion of self-reactive lymphocytes, which in turn can lead to tissue damage and the manifestation of an autoimmune disease. Autoimmune diseases are broadly categorized into systemic and organ-specific disorders. Systemic lupus erythematosus (SLE) and multiple sclerosis (MS) are examples of systemic and organ-specific autoimmune diseases, respectively.

In the last several years, there has been increasing realization that the expression of a target autoantigen involved in an organ-specific autoimmune disease is not necessarily restricted to that particular tissue. Instead, the autoantigen is either expressed ubiquitously or also expressed within the thymus (ectopic expression). The latter observation represents a paradigm

shift in our understanding of the induction of self-tolerance to tissue-specific antigens. It is now known that many target self-antigens relevant to the pathogenesis of autoimmunity are efficiently expressed within the thymus and that their expression is controlled in part by a transcription factor named autoimmune regulator (*aire*). Furthermore, both humans and mice deficient in the *AIRE* gene exhibit signs of systemic autoimmunity. The human disorder is referred to as the autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy syndrome (APECED). In regard to the mechanisms of peripheral tolerance, a deficiency of a subset of T regulatory cells (Treg, CD4⁺CD25⁺ T cells) also results in autoimmune manifestations. These Treg are characterized by the expression of Foxp3, a unique transcription factor that is a member of the forkhead/winged-helix family of transcriptional regulators. Patients lacking the *FOXP3* gene are deficient in Treg and exhibit features of immune dysregulation, polyendocrinopathy, enteropathy, X-linked (IPEX) syndrome. Thus, in a healthy individual, both central and peripheral tolerogenic mechanisms play critical roles in the induction and maintenance of self-tolerance and, thereby, in the prevention of autoimmunity.

Cells Exposed to Stressful Stimuli Upregulate the Expression of Stress Proteins

Stress proteins (previously known as heat shock proteins; Hsps) are ubiquitous cellular proteins whose expression within cells is upregulated in response to a variety of stressful stimuli, for example, increased temperature, oxidative stress, nutritional deficiency, viral infection, tumor necrosis factor (TNF)- α , endotoxin, adrenergic stimuli, and ultraviolet irradiation. These stimuli may be part of environmental stress or pathological states. The Hsps thus induced protect cells from cellular injury including stress-induced apoptosis. Hsps are highly conserved in prokaryotes as well as eukaryotes, and they are grouped into several families based on their molecular weight ([Table 1](#)). Hsps are localized in various intracellular compartments and function as molecular chaperones, which take part in the assembly, folding, and translocation of cellular proteins ([Table 2](#)). Because Hsps are primarily intracellular proteins, their release from necrotic cells into the extracellular environment indicates nonphysiological tissue damage, and such release of Hsps can induce a range of biological responses.

Table 1 Mammalian heat shock protein (Hsp) families and their cellular location and function^a

<i>Hsp family/members</i>	<i>Localization</i>	<i>Functions</i>
Small Hsps		
Hsp10	Mitochondria	Co-chaperone for Hsp60 activities
α B-crystallin	Cytoplasm	Cytoskeletal stabilization
Hsp27	Nucleus/cytoplasm	Actin dynamics
Hsp32	Cytoplasm	Heme metabolism, antioxidant properties
Hsp40		
Hsp40	Nucleus/cytoplasm	Binds to non-native proteins, regulates the activity of Hsp70
Hsp47	Endoplasmic reticulum	Processing and/or secretion of collagen
Hsp60		
Hsp60	Mitochondria	Both involved in protein folding and assembly
TCP-1	Cytoplasm	
Hsp70		
Hsp70	Nucleus/cytoplasm	Hsp70 regulates HSF-1 activity and Hsp gene transcription
Grp78/Bip	Endoplasmic reticulum	All: Prevent aggregation of unfolded proteins
Grp75	Mitochondria	Bind ATP and show ATPase activity
Hsp90		
Hsp90 (α and β)	Cytoplasm	Bind to other proteins and regulate protein activity
		Assembly and folding of newly synthesized proteins
Grp94/gp96/Hsp100	Endoplasmic reticulum	Prevent aggregation of refolded proteins
Hsp110		
Hsp110 (human)	Cytoplasm/nucleolus	Thermal tolerance
Apg-1 (mouse)	Cytoplasm	Protein refolding
Hsp105	Cytoplasm	

^aApg-1, Autophagy-1, a protein kinase essential for autophagy; ATP, adenosine triphosphate; Bip, immunoglobulin heavy chain binding protein; Grp, glucose-regulated protein; HSF-1, heat-shock factor 1; Hsp, heat shock protein; TCP-1, tailless complex polypeptide.

Table 2 Effects of heat shock proteins on the immune system^a

<i>Immunological effects</i>	<i>Hsp involved</i>	<i>Specific action and cell types</i>
Antigen processing and presentation	Hsp70	Peptide loading and antigen processing of MHC class I molecules
		Interaction with misfolded MHC class II and retention in the ER
	Hsp90	Peptide transport and loading of MHC class I in the ER
	Bip and Calnexin	Assembly of MHC class I and class II molecules in the ER
Expression of intercellular signaling molecules	gp96	Interaction with misfolded MHC class II and retention in the ER, peptide loading of MHC class II molecules
		ICAM-1 and VCAM-1 expression on vascular endothelial cells
	Mycobacterial Hsp60	
	Chlamydial and human Hsp60	E-selectin, ICAM-1, and VCAM-1 expression on vascular endothelial cells
Cytokine production	Hsp60	Production of IL-1 α , IL-6, IL-12, IL-15, nitric oxide, and TNF- α by monocytes and macrophages
		IFN- γ production by T cells
	Hsp60 and Hsp70	IL-6 production by vascular endothelial cells
		IL-6 production by smooth muscle cells
Target cell lysis	Hsp70	Tumor cells
Lymphocyte homing	Ubiquitin	Lymphocyte receptor involved in the interaction with high endothelial venules, thereby in lymphocyte homing

^aBip, immunoglobulin heavy chain binding protein; ER, endoplasmic reticulum; Hsp, heat shock protein; ICAM-1, intercellular adhesion molecule-1; IL, interleukin; INF, interferon; MHC, major histocompatibility complex; TNF, tumor necrosis factor; VCAM-1, vascular cell adhesion molecule-1.

Hsps can influence several functions of the immune system such as antigen processing and presentation, cytokine production, expression of intercellular signaling molecules, lymphocyte trafficking, and target cell lysis (Table 3). Hsps also can serve as

immunodominant antigens, and one hypothesis underlying the immune alterations induced by Hsps invokes immunological cross-recognition between the mammalian and the microbial homologs.

Hashimoto's thyroiditis	—	Human Hsp60

^aBip, immunoglobulin heavy chain binding protein; DDA, dimethyl dioctadecyl ammonium bromide; Hsp, heat shock protein.

Tolerance to Stress Proteins Is Incomplete

Despite the existence of several mechanisms for tolerance induction against self-proteins, the presence of self-Hsp-specific T and B lymphocytes in the mature repertoire has been reported in healthy individuals. The presence of self-hsp60-specific T cells was demonstrated in inbred Lewis rats by immunization with mammalian hsp60 using either vaccinia virus or DNA encoding human hsp60 or using rat hsp60 that is 98% homologous to human hsp60. In this context, it has been shown that Hsps are expressed at high levels in the normal thymus. Moreover, the transgenic overexpression of mouse hsp60, in the thymus failed to eliminate T-cell responses to self-hsp60 following hsp60 immunization. Thus, in contrast to other antigens that are tolerogenic at low levels of thymic expression, hsp60 failed to delete antigen-specific T cells even at high levels of expression within the thymus.

Endogenous hsp60 Can Be Processed and Presented to Antigen-Primed T Cells

Although Hsps are intracellular proteins, they can be efficiently expressed on the cell surface as peptide–

major histocompatibility complex (MHC) complexes. For example, the T cells raised in the Lewis rat against the disease-protective C-terminal epitopes of rat hsp60 can be restimulated *in vitro* in a proliferation assay when cocultured with heat-stressed but not unstressed syngeneic APCs in the absence of exogenous antigen, suggesting that the endogenous hsp60 can both be upregulated and be processed and presented by the APCs to activate antigen-primed T cells. The processing and presentation of hsp60 via class I pathway has also been documented. Cytotoxic T lymphocytes (CTL) specific for mycobacterial hsp60 were shown to recognize stressed macrophages in the absence of exogenously added antigens, suggesting that endogenous self-hsp60 is presented in the context of MHC class I molecules to the CTL. Furthermore, the CTL-mediated lysis of stressed macrophages was suppressed by hsp60-directed antisense oligonucleotides, thereby confirming the specificity of the CTL for hsp60.

The breakdown of self-tolerance leading to the induction of antiself immune response is typically associated with the initiation of autoimmunity. However, studies by different investigators have shown that antiself-hsp60 immunity may be immunosuppressive and beneficial against autoimmunity. Lewis rats

immunized with either self-hsp60 (rat hsp60) or its homologous human hsp60 are protected against subsequent induction of adjuvant arthritis (AA). Furthermore, this protection can be adoptively transferred to naïve Lewis rats through the T cells of protected rats. Similarly, other Hsps in addition to hsp60 possess immunoregulatory activity.

Oxidative Stress Influences Several Components of the Immune System Pertaining to Self-Tolerance and Autoimmunity

Oxidative stress results from the increased production of oxidants, reduced generation of antioxidants, or failure to repair an oxidative damage. The damage to cells/tissues is caused by reactive oxygen species (ROS) comprised of free radicals, peroxides, and so forth (e.g., hydroxyl radical, hydrogen peroxide, and peroxynitrite). ROS can be derived from endogenous (e.g., metabolic reactions within the mitochondria or the liver detoxification pathways) or from exogenous (e.g., environmental pollutants or microbial infections) sources. ROS produced during oxidative stress can modulate a wide variety of cellular functions through the regulation of NF- κ B. Some of the processes influenced by oxidative stress and ROS are summarized in [Figure 1](#).

It has been observed that oxidative stress induces hyporesponsiveness in T lymphocytes, which in turn

correlates with ROS-dependent protein alterations including structural modification of crucial T-cell receptor (TCR) signaling molecules. Also reported is the inhibition of activated/memory T cells by oxidative stress, which is associated with a block of NF- κ B activation. In addition, a predominant decrease in Th1 (but not Th2) cytokine production was observed in the memory/effector subset compared to naïve T cells. ROS can also influence the activity of the major professional APCs such as dendritic cells (DCs). It is known that immature DCs are tolerogenic, whereas mature DCs are immunogenic. In this context, it has been shown that ROS can significantly decrease the tolerogenic activity of DCs. In one study, this inhibitory effect of ROS was shown to be overcome by treatment with soluble CTLA-4. The precise significance of this interrelationship has not yet been fully defined.

Oxidative stress and ROS have been implicated in the pathogenesis of various autoimmune diseases, including arthritis and diabetes mellitus. Oxidative stress can modulate the intracellular levels of G-protein-coupled receptor kinases (GRKs), which in turn influence the activity of G-protein-coupled receptors (GPCRs). It has been observed that the levels of GRK2 and GRK6 are decreased in lymphocytes of patients with rheumatoid arthritis (RA) as well as of rats with AA. Similarly, decreased GRK2 levels have also been found in splenocytes of rats with experimental autoimmune encephalomyelitis (EAE).

Figure 1 Oxidative stress and its influence on physiological and pathological immune processes. Oxidative stress has been implicated in a large variety of biological reactions. AA, adjuvant arthritis; CTLA-4, cytotoxic T lymphocyte associated-4; DC, dendritic cells; EAE, experimental autoimmune encephalomyelitis; GPCR, G-protein-coupled receptor; GPI, glucose-6-phosphate isomerase; GRK, G-protein-coupled receptor kinase; Hsp, heat-shock protein; NF- κ B, nuclear factor kappa B; RA, rheumatoid arthritis; SOCS, suppressor of cytokine signaling; Th1, T helper 1; Th2, T helper 2.

GRKs are involved in modulating leukocyte chemotaxis into the target organs that constitute the sites of autoimmune inflammation (e.g., the joints in RA and the brain in EAE). Interestingly, peptides containing defined sequences of the kinase-substrate interaction site of GRK2/3 show antidiabetic activity in animal models of type 2 diabetes, supporting the likely therapeutic significance of GRKs in some other diseases as well.

Hypoxia is a characteristic feature of joints observed in both RA patients as well as experimental models of arthritis. Interestingly, it is associated with increased expression of glucose-6-phosphate isomerase (GPI), which has been shown to be one of the target autoantigens in autoimmune arthritis in K/BXN mice. These mice possess a TCR that is transgenic for an epitope within ribonuclease, but it fortuitously cross-reacts with the ubiquitously expressed protein, GPI. An immune response to GPI has been observed in K/BXN mice as well as in RA patients, particularly those with extra-articular complications.

ROS have been shown to have a toxic effect on the β islets of the pancreas, and thereby they have been implicated in the pathogenesis of type 1 diabetes mellitus. Interesting, Hsps can offer protection against ROS-mediated damage to β islets. Another protective pathway in β islets involves the suppressor of cytokine signaling (SOCS)-3. Similarly, SOCS-1 plays a role in the pathogenesis of arthritis, and SOCS-1 deficiency results in severe synovial inflammation and joint destruction. SOCS proteins can be induced by a variety of stimuli, particularly various cytokines, and they regulate cytokine signaling as well as a wide variety of pathways relevant in inflammatory diseases of infectious and autoimmune origin. The pro-inflammatory cytokine interferon (IFN- γ) induces the expression of SOCS-1 and -3.

Oxidative stress may also contribute to an anxious behavior. Furthermore, the levels of two enzymes (glyoxalase 1 and glutathione reductase) that influence oxidative stress also positively correlate with the level of anxiety. Considering the relationship between stress and autoimmunity, this finding provides one of the molecular links between stress and behavior (anxiety) associated with autoimmunity.

Neural Immune Interactions and Their Relevance to Autoimmunity

Several lines of evidence emphasize the interplay between, and cross-regulation of, the activities of the nervous system and the immune system. The nervous system influences the immune system primarily via the hypothalamic-pituitary-adrenal (HPA) axis, the

hypothalamic-pituitary-gonadal (HPG) axis, and the chemical mediators of the autonomic nervous system, whereas the immune system modulates the activities of the neural system via cytokines and the vagus nerve. In experimental models of autoimmune diseases and human subjects, an inadequately functioning or blunted HPA axis has been associated with increased susceptibility and/or enhanced severity of autoimmune diseases such as RA and MS. In some cases, the baseline HPA axis activity in the disease-susceptible versus disease-resistant individuals was comparable, but the dysfunction of the HPA axis was manifest on an exposure to the stressful or inflammatory stimuli. Because the stress response intimately involves the components of the HPA and HPG axes, it is apparent that chronic physical and psychosocial stresses constitute one of the factors that have been implicated in the initiation and aggravation of an autoimmune condition.

The underlying hypothesis involving the HPA axis is that susceptibility to autoimmune diseases may be related to inadequate responsiveness of the HPA axis to stressful stimuli such that there is a decreased secretion of cortisol and other biomolecules that are normally required to downregulate the immune responses. Consequently, unchecked immune reactivity leads to the induction of anti-self-directed T cell and/or antibody responses, which if propagated, may eventually lead to autoimmunity. In support of this proposition, studies in the rat model of AA have revealed that susceptible rat strains (e.g., Lewis and DA rats) have impaired HPA axis compared to resistant rat strains (e.g., Fischer F344 and BN rats) that display an aggravated HPA axis response. Interestingly, chemical/pharmacological or surgical manipulations aimed at altering the HPA axis activity in these rats also resulted in a corresponding change in the pattern of susceptibility/resistance to AA. The complementation of the HPA axis activity by the administration of glucocorticoids or transplantation of the hypothalamus from the resistant rat strain into susceptible rat strain led to acquired resistance to AA, whereas interference with HPA axis activity rendered the resistant rat strain susceptible to AA. Such differences in HPA axis activity in response to stress or inflammatory stimuli have also been observed in male versus female rats, with the HPA axis response impaired in female rats relative to male rats. These results suggest that differences in HPA axis responsiveness might contribute to the higher incidence of autoimmune diseases observed in females compared to males. An additional link between gender-related hormones and susceptibility to autoimmunity is provided by the observation that androgens exert a suppressive, anti-inflammatory effect on T-cell and

antibody responses, whereas estrogens tend to enhance immune reactivity, particularly antibody responses.

The evidence to support a direct association between HPA axis and autoimmune susceptibility in patients with autoimmune diseases is not as clear as in animal models of these diseases. Nevertheless, clinical histories and the examination of the parameters reflecting HPA axis activity support the idea that HPA axis activity is impaired in diseases such as RA and MS. For example, the decreased secretion of cortisol following HPA axis stimulation, reduced number of glucocorticoid receptors on specific cell types, decreased androgen levels, impaired growth hormone response, and inadequately low ratio of steroid hormones to interleukin (IL-)6 and TNF- α have been observed in RA patients. In addition to the HPA axis, the dysregulated autonomic nervous system is also a critical modifier of autoimmune susceptibility and chronicity of the autoreactive immune response. A cholinergic anti-inflammatory pathway involving the vagus nerve is believed to represent a physiological pathway for the detection of inflammatory stimuli via the afferent vagus and the corresponding regulation of the cytokine (TNF- α) response of macrophages via the efferent vagus. The nicotinic acetylcholine receptor α 7 subunit expressed on the macrophage plays a critical role in this pathway. Taken together, it is evident that other factors in addition to the HPA axis and the autonomic nervous system, such as genetic and environmental factors, also play an important role in determining susceptibility/resistance to autoimmunity.

Immunoregulatory and Therapeutic Approaches Based on Biomolecules and Intracellular Pathways Involved in the Stress Response

1. *Altering the cellular levels of Hsps.* Taking into consideration the chaperone function of Hsps in protecting other proteins from damage in stressed cells as well as the finding that anti-Hsp immunity can be immunoregulatory in nature, the expression of cellular Hsps can be induced physiologically or pharmacologically, or by direct administration of a specific Hsp for a beneficial effect in suppressing autoimmunity. For example, the levels of endogenous Hsps can be increased by hyperthermia, geldanamycin, geranylgeranylacetone, cyclopentenone prostanoids, certain heavy metals, salicylates, or dexamethasone. On the other hand, the expression of Hsps can be decreased by retinoic

acid, bioflavonoid compounds, or 15-deoxyspergualin, and this approach may prove useful in augmenting immunity as desired for antitumor immunity.

2. *The use of antioxidants.* A wide variety of synthetic and naturally occurring compounds have been used to counter the cellular effects of oxidative stress and ROS. These compounds possess antioxidant properties. Vitamin E, vitamin C and β -carotenes are well-known antioxidants. The extracts of certain plants have also been found to possess potent antioxidant activity by scavenging free radicals leading to anti-arthritis activity in the rat model of AA. These include pumpkin seed oil, *Semecarpus anacardium*, and *Trewia polycarpa*. In addition, Meloxicam modulates oxidation status and is beneficial in suppressing AA.
3. *Interventions aimed at HPA-HPG axes and the autonomic system.* Pharmacological and surgical procedures have been employed in experimental systems to reconstitute or enhance the activity of the HPA and HPG axes and to alter the activity of the autonomic system and cytokine (TNF- α) secretion by macrophages via the stimulation of the vagus nerve. The administration of androgens to strike a sex hormone balance is another modality that is being exploited for the control of RA, particularly in male patients.
4. *Targeting the stress signaling pathways.* The synovial membrane of arthritic joints is under a variety of stresses: oxidative stress, pro-inflammatory cytokines, heat-stress, and shear stress. Multiple cell surface-resident and intracellular molecules are involved in stress signaling pathways in the milieu of inflammatory synovitis, and these signaling pathways represent novel and promising targets for the control of RA and other autoimmune diseases.

Fear Conditioning

Avoidance in Psychiatric Disorders

Closing Comments

Glossary

Active avoidance

A neutral conditioned stimulus (CS; tone, light) is used to announce an aversive unconditioned stimulus (US; electric footshock). In response to the CS, animals learn and perform spatial motor patterns in order to avoid deleterious consequences of the US.

Anxiety

State of intense apprehension, uncertainty, and fear resulting from the anticipation of a threatening event or situation, often to a degree that normal physical and psychological functioning is disrupted.

Approach-avoidance conflict

Situation in which the goal has both positive and negative factors. It is the most typical short term conflict encountered and the most anxiety provoking.

Coping

An individual's behavioral and physiological response repertoire to master a challenge.

Fear

Feeling of agitation and dread caused by the presence or imminence of danger.

Fear conditioning

A neutral conditioned stimulus (CS; tone, light, context) is paired with an aversive unconditioned stimulus (US; electric footshock, air blast), that cannot be avoided. After a single or a few pairings, the CS alone is capable to induce behavioral and physiological fear responses.

Innate (inborn) fear

Needs no previous experience, is often species specific and directed towards actual or potential threats (heights, light, smell, taste, predator).

<i>Inhibitory avoidance (also known as passive avoidance)</i>	The inhibition of innate activities or learned habits, which have led to aversive consequences.
<i>Negative reinforcement</i>	The withdrawing of aversive stimuli (actual or imagined) after the individual has made the appropriate response.

Avoidance Conditioning

Learning about the environment, its physical and social relationships includes the conditioning of stress-induced avoidance behavior, its neuroendocrine and other physiological components. Aversive events are actively avoided. Individuals use distinct behavioral patterns that are determined by genetics, (early) life experiences, and the environment.

Coping strategies serve to reduce or eliminate stress. As an innate defense mechanism, avoidance behavior protects the organism from harm, allows learning of new features of the social and physical environment, and is thus, central for survival and development of the individual. However, when getting pathological, i.e., out of context and magnitude, the price of avoidance is a denial or distortion of reality.

Principles of Avoidance Conditioning

Avoidance and fear are closely related. Placing an animal in a novel environment activates the stress system (surge of corticosteroids and catecholamines), initiates exploratory activity, which is, at the same time, opposed by the fear evoking properties of the situation, e.g., open space, bright light, and another animal. This apparently simple event of novelty initiates an approach–avoidance conflict. Opposite avoidance responses might be observed: immobility (freezing, crouching) or movement (fight-or-flight responses; running, jumping).

Animals and humans learn about the spatial and temporal characteristics of the environment and their emotional consequences. Electric shock is the most frequently used aversive stimulus (stressor) in the laboratory. Avoidance paradigms provide excellent models of specific and successful behavioral coping with stress.

Inhibitory avoidance conditioning requires the inhibition of innate activities or learned habits, which have led to aversive consequences. It is one of the most common modifications of behavior induced by aversive experience. In active avoidance conditioning, individuals learn that signals announce an aversive stimulus. The aversive consequences of this stimulus can not only be terminated with the appropriate active behavior, but also avoided completely by responding with this active behavior already to the

signal. The terminology, inhibitory and active avoidance is somewhat confusing since both paradigms require active processes to avoid and thus reduce the (anticipated) adverse consequences.

Avoidance and Stress Hormones

A prominent hormonal stress response, namely the rise in plasma corticosterone as a consequence of the activation of the hypothalamic-pituitary-adrenal (HPA) axis, is not only a useful marker of the stress experienced by the individual, but also predictive for the strength of the avoidance conditioning and crucial for the extinction of avoidance behavior. Interindividual differences have to be taken into account.

Experiments performed in the 1970s demonstrated that avoidance learning and its extinction are strongly affected by stress hormones. Acquisition as well as extinction of avoidance behavior is facilitated by corticosterone, while the lack of corticosterone (due to removal of the adrenals) inhibits the extinction process of a conditioned avoidance response. Complex interactions between corticosteroids and catecholamines have been described then and are discussed with new interest nowadays.

Active Avoidance Conditioning

The first stage of avoidance learning is usually escape, whereby the reaction of the animal terminates the encounter with the aversive stimulus; i.e., negative reinforcement due to shock reduction. With continued training, anticipatory reactions appear: the animal already responds to the stress-announcing stimulus, and thus, avoids the shock altogether. Due to the total elimination of aversive consequences fast extinction of avoidance behavior might be expected. This is not the case: active avoidance responses are very persistent. It is thought that anticipation of the signal stimulus elicits a motivational state of fear and the subsequent avoidance response decreases fear, i.e., negative reinforcement due to fear reduction. Taken together, negative reinforcement processes are thus, responsible for the acquisition and maintenance of active avoidance behavior.

Spatial paradigms have been developed to study active avoidance in rats and mice. For example, in the shuttle box, the rodent can avoid painful electrical footshock by shuttling from one (aversive, shock) compartment to the other (safe, no shock). Usually, the occurrence of the shock is preceded by a tone or light stimulus, so that the animal can learn to predict the aversive properties of the compartment, and move to the safe side. Since there is no permanently safe area, it takes the animals many trials to learn. Avoidance is acquired faster in the run-way apparatus,

which has fixed safe areas. It is essential to all active avoidance paradigms that the animal learns as soon as possible that the aversive situation can be escaped. Otherwise, maladaptive habits are conditioned.

The acquisition (learning) phase of active avoidance behavior in rats is paralleled by high concentrations of the plasma corticosterone. During perfect avoidance, plasma corticosterone levels decrease and remains low. Evidence suggests that active avoidance behavior reduces the aversive character of the situation. Interesting is the fact that preventing the rats from making the avoidance response leads to a high rise in plasma corticosterone, even if no further footshock is experienced. In the 1970s, observations in rats showed that behavioral controllability and predictability of a stressful situation determined the magnitude of the rise in plasma corticosterone levels. If rats were able to avoid painful electroshocks or to predict their occurrence, plasma corticosterone did not rise as high as in the case of unavoidable or unpredictable shock. The latter condition is used in the so-called learned helplessness paradigm that is considered as an animal model for depression and also posttraumatic stress disorder (PTSD).

Inhibitory Avoidance Conditioning

Innate behavior or learned habits that had been paired with aversive consequences in the past will not be expressed. In the future, inhibition of the innate behavior will keep the unpleasant consequences away, i.e., negative reinforcement. Inhibitory avoidance is a highly emotional learning situation. In fact, it is a conflict situation for the individual, which will display patterns of approach and avoidance of the space or object of preference (approach-avoidance conflict).

In contrast to the extended training period required for active avoidance learning, inhibitory (or passive) avoidance paradigms are usually based on a single learning trial followed by a retention test at defined intervals after training. They have the advantage that neurobiological processes underlying learning and memory are defined within a certain timeframe and thus, can be estimated and modulated accordingly. It is a real pro for studying molecular mechanisms of avoidance.

Experimental paradigms in rodents use the innate preference, for example, dark-to-light (step-through task), high-to-low places (step-down task) followed by an aversive stimulus like footshock. The animal will actively control – inhibit – the performance of the innate pattern in the future. To gain reproducible results, the active behavior must be well defined and the aversive stimulus closely associated in time

with the innate behavior. Immobility behavior is observed, but it is not the typical avoidance response. Latency of avoidance is the most frequently used measurement.

A distinct paradigm of inhibitory avoidance is the so-called conditioned taste aversion. This is based on bait shyness, i.e., limited ingestion of novel foods and the association of their properties with delayed gastrointestinal consequences, and preference for sweet taste. The innate preference of rodents for sweet taste is followed by illness induced by substances like lithium, cyclohexamide, but also amphetamine and morphine. A single association between the sweet-tasting substance and the illness-inducing drug induces avoidance of the preferred taste. Conditioned taste aversion can also be studied in 1-day-old chicks.

Activation of the stress systems takes place in response to the aversive stimulus, affecting memory consolidation. Both corticosteroids and catecholamines are important for optimal memory performance. Specifically increased corticosteroid hormone levels within the context and close-in-time to the learning situation facilitate the memory of the negative event. The result is an active behavioral stress management, the inhibition of the innate/preferred response which is observed during retention test.

Fear Conditioning

Fear-conditioning paradigms are used to investigate the conditioning of emotional processes. During conditioning, the individual cannot avoid the aversive stimulus, which is usually announced by a signal. During retention testing, the signal itself elicits the fear response, which is invariably immobility (freezing), accompanied by high blood pressure and tachycardia.

In fear-conditioning paradigms, a meaningless stimulus (tone or light) is paired with an electric footshock. After one or several pairings, the tone or light becomes the conditioned stimulus. The retention test takes place in the absence of the footshock, at defined times after training. While in so-called classical or Pavlovian conditioning only defined cues are used, fear-conditioning paradigms have incorporated the complexity of the physical or social environment. These latter paradigms are called contextual fear conditioning. Anatomical pathways are well described (emotional response circuits, including amygdala, brainstem nuclei, hippocampus, and prefrontal cortex). Likewise, molecular mechanisms have been reported. Knowledge of neuroendocrine changes include the rise in plasma prolactin, adrenocorticotropin, corticosterone, and catecholamines. Plasma

corticosterone levels in rats are positively correlated with the extent of contextual conditioned fear.

Freezing is of obvious adaptive value. It not only decreases the probability of acoustic or visual detection, but also conserves energy in situations where action is inefficient, like in fear conditioning. Formerly, freezing was considered as a nonfunctional coping response. Individuals may use one or the other coping strategy, depending on genetic make-up and life experiences, influenced by the physical and social environment. Active avoidance paradigms select for active fight-or-flight strategies, while fear-conditioning paradigms select for passive, conservation and withdrawal-oriented approaches.

Avoidance in Psychiatric Disorders

Avoidance is a central feature in anxiety disorders like generalized anxiety, phobias, PTSD, and obsessive-compulsive disorder (OCD).

A person suffering from OCD is subjected to actions and/or thoughts that he/she finds undesirable but is unable to prevent. Simple gestures to complex rituals are carried out to avoid fear or unacceptable impulses. Any behavior that is associated with the reduction or avoidance of fear tends to be highly persistent in the presence of the stimuli involved. Preventing the performance of the obsessive-compulsive action or thoughts, results in acute discomfort or panic, similar to animals, which are prevented to display their conditioned avoidance response.

According to the *Statistical Manual of Mental Disorders – 4th Edition* (DSM-IV), the characteristic symptoms of PTSD, intrusion, avoidance, and hyperarousal result from previous exposure to an extreme trauma and include persistent re-experiencing of the traumatic event. For example: the person commonly makes deliberate efforts to avoid thoughts, feelings, or conversations about the traumatic event and avoiding activities, situations, or people who arouse recollections of it. Interference and deterioration of interpersonal relationships are the consequences.

Animal Models

Each of the three conditioning paradigms, active and inhibitory avoidance, and fear conditioning, provide aspects for potential animal models of various forms of human anxiety disorders. At present, none of the known animal models stands exclusively for one psychiatric disorder as they are currently defined in the DSM. For example, learned helplessness, the response to inescapable and uncontrollable shock, had initially received the greatest attention as animal model for PTSD. Nowadays, it is more accepted as model for depression. The (causal) relation between stress

hormones, PTSD, and the design of animal models is in the center of interest of preclinical science and clinical applications.

The wide variety and complexity of avoidance symptoms in anxiety-related disorders supports the general belief of underlying avoidance and fear-conditioning processes, indicating at the same time the difficulty for efficient behavioral and cognitive therapeutical approaches.

Closing Comments

Avoidance has been discussed mainly as an adaptive response of the individual to environmental challenges. Fear-related avoidance behaviors are of high relevance for physical survival and social competence. While inhibitory avoidance is as fast acquired as fear conditioning (one trial is often enough), active avoidance needs training (repetitions). Conditioned responses are hard to extinguish. Out of a variety of anxiety and other psychiatric disorders, PTSD and OCD were selected as typical examples with symptoms of pathological avoidance. It is most likely that physiologically functional and pathologically maladaptive avoidance use the same brain circuits. Animal models can contribute and elucidate the (molecular) mechanisms of anxiety. Stress and specifically the (re)activity of corticosteroid hormones are critically involved in the acquisition and persistence of conditioned avoidance and fear responses, thus proving their relevance for the development and course of several psychiatric diseases with core symptoms of avoidance.

Conclusions

Glossary

*Behavioral
analysis*

The detailed analysis of a behavior, which is considered essential before treatment is undertaken.

*Classical
conditioning*

A basic form of learning where a neutral stimulus, which is presented repeatedly with a stimulus that elicits a particular response, eventually begins to elicit that response.

Introduction

The term behavior therapy is commonly used to refer to a particular approach to the treatment of psychological disorders. It has several key features. Behavior therapy sees many psychological problems as instances of maladaptive learning or, in some cases, failure to learn. The focus in behavior therapy is the presenting problem itself. It is not assumed that the presenting problem is a manifestation of an underlying primary problem. The aim of behavior therapy is to modify the problem behavior at a behavioral level, using behavioral means. In this endeavour, the principles of learning, and other methods and findings of experimental psychology, are utilized. Specifically, the principles of classical conditioning and those of

operant, or instrumental, conditioning are key cornerstones of this approach.

Other features of behavior therapy include the emphasis on the detailed analysis of the problem behavior (in terms of stimuli, responses, consequences, etc.), the key role given to measurement and quantification, and the use of an experimental approach, where treatment follows a hypothesis-testing paradigm. This also includes a strong emphasis on outcome evaluation.

Historical Development

Historically, behavior therapy developed over a period of time, culminating in its full emergence as a major psychological treatment approach in the 1950s. The basic concept of behavior change via behavioral means is of course very old, and there are examples of this from very early times, including the use of behavioral techniques in early Buddhism two-and-a-half millennia ago in India and in Rome around the beginnings of the Christian era. However, the key developments in the context of modern psychology can be traced to the work of a few key individuals, including John B. Watson, who demonstrated the applicability of learning principles in the understanding of the development of irrational fears. Watson and Rosalie Rayner, in 1920, created new fears in an 11-month-old child named Albert using classical conditioning principles. Four years later, Mary Cover Jones – one of Watson's students – published what might be described as the first formal application of learning principles to the treatment of a problem behavior. A 3-year-old boy, Peter, with a fear of rabbits was treated via the association of the feared stimulus with other positive and pleasant stimuli.

In the 1940s and 1950s much work along these lines was done in South Africa, mainly by Joseph Wolpe. Wolpe, who later emigrated to the United States, undertook serious experimental work – first with animals and then with human subjects – on the modification and elimination of maladaptive responses. His book, *Psychotherapy by Reciprocal Inhibition*, published in 1958 by Stanford University Press, is widely regarded as a landmark publication signaling the emergence of behavior therapy as a major therapeutic approach. Wolpe's work was supplemented by further work, both theoretical and empirical, by other leading figures such as Hans Eysenck, Monte Shapiro, Victor Meyer, and others in London and by Stanley Rachman, an associate of Wolpe who emigrated from South Africa to England in the early 1960s and joined Eysenck.

An equally significant contribution to the development of behavior therapy was made by B. F. Skinner,

whose book *Science and Human Behavior* (1953, Macmillan, New York) is also regarded as a classic in this field. The work of Skinner and associates concentrated on the use of operant conditioning principles, recognizing the key role of consequences in the maintenance and modification of behavior.

The establishment of *Behaviour Research and Therapy* in 1963 as a journal devoted to the field behavior therapy was another major step in the establishment of behavior therapy.

More recent developments have expanded and widened the scope and basis of behavior therapy. In the early stages, behavior therapy, drawing on the principles of classical conditioning, was used for what were then called 'neurotic disorders.' The largest group of patients treated in the early days in this way were those with phobias, or irrational and maladaptive fears. In fact, most of the cases described in Wolpe's 1958 book were individuals suffering from phobias. Those with obsessive-compulsive problems, sexual difficulties, and addictions were also treated. Operant conditioning principles were used to help in the management of behavioral problems in children and to modify problem behaviors in those with pervasive learning disability (mental retardation) and with chronic psychotic illness. These early developments were later supplemented (1) by the ideas of social learning theory, which pointed out that human behavior change takes place not just with direct experience but also through vicarious learning and social transmission and (2) by ideas and techniques of cognitive psychology and cognitive therapy, which showed the importance of cognitions (thoughts, attitudes, beliefs) in determining and/or influencing human behavior. The incorporation of cognitive therapy principles developed by Aaron T. Beck in Philadelphia and others eventually led to what is today referred to by many as cognitive behavior therapy.

Techniques of Behavior Therapy

Behavior therapy is widely applied today for a range of problems. It is considered to be a major, robust approach to helping people to get over problem behaviors and develop more adaptive ones. Some of the major behavior therapy techniques are described briefly in this section.

Exposure Therapy

This is the main approach used for phobias. The principle here is that exposure to the feared – and avoided – stimulus, in therapeutic conditions, leads to a reduction and eventual elimination of fear. This may be done either in real life (*in vivo*) or in imagination or fantasy. The client is exposed in a graded series

of steps to the fear stimulus or situation. As an anxiety-countering strategy, deep muscle relaxation may be used. Clients are usually treated individually, but group treatments are also undertaken. In recent years, clients have also been taught to engage in this type of exposure therapy by themselves, i.e., self-managed exposure therapy, after assessment by a qualified therapist and agreement on a plan of treatment.

In contrast to the graded exposure approach, intensive and/or prolonged exposure is also used. In the early days, this was generally known as flooding. *In vivo* flooding and imaginal flooding are both used. Essentially, the client is exposed to the fear-arousing situation for a prolonged period of time, which is done without a graded, step-by-step approach. Highly anxiety-arousing situations are used from the beginning. A treatment session usually ends when the client's initial high anxiety has subsided to a significant degree.

Modeling

In modeling, the client is exposed to other individuals, or models, engaging in the target behaviors in an appropriate, nonanxious manner. Modeling is used in fear reduction. The active participation of the client is a key aspect. Modeling is also used widely in the treatment of those who have difficulties in assertiveness and other social skills. Again, participant modeling, rather than simply observing the models, is needed to achieve the desired changes.

Response Prevention

This is a technique that is usually employed in conjunction with exposure. The best known application of this approach is in the treatment of compulsive behaviors in obsessive-compulsive disorder. The client is exposed to situations that arouse anxiety and create an upsurge of the urge to engage in the target compulsive behavior. For example, a client with contamination fears and associated compulsive hand-washing rituals may be exposed to items which he or she believes are contaminating, such as dirty table surfaces or door handles in a public convenience. This exposure leads to high anxiety and to a high urge to engage in a cleansing, hand-washing compulsion. However, as part of the prearranged treatment plan, the client refrains from engaging in this compulsive behavior. The compulsive urge and the anxiety both gradually dissipate with time, and the session is ended when a significant reduction is achieved. Repeated sessions lead to progressively lower anxiety and less strong compulsive urges.

Response prevention following exposure is also used with clients with alcohol problems, drug addiction, and compulsive binge eating, among others.

The Use of Reinforcement

Reinforcement is the strengthening of a behavior so that the probability of its occurrence is enhanced. Using reinforcers, or rewards, to strengthen desirable behavior is a major behavior therapy technique. There are two types of reinforcers. A positive reinforcer is something pleasant or welcome that is presented as a consequence of the desired behavior being performed. For example, a child may be given a sweet as a reward each time he puts on his socks by himself. A negative reinforcer is something unpleasant and/or unwelcome that is removed, or avoided, as a consequence of the target behavior being carried out.

It is common in behavior therapy to use social reinforcers as a major means of positive reinforcement of desired behaviors. These include verbal praise, approval, and attention.

Token Economics

A token economy is a whole system of reinforcement used for motivating clients. For example, a group of children in a class or a group of chronic schizophrenic patients in a large hospital ward may be helped in this way. Desired target behaviors are immediately reinforced with tokens: plastic chips, stars on a chart, or points. Maladaptive behavior can lead to the loss of tokens. The tokens are exchangeable for real reinforcers; these are called back up reinforcers in this context. For example, 10 tokens may be exchanged for a bar of chocolate. A token economy program has a set of detailed and explicit rules and procedures that specify how tokens are to be earned and how they are to be exchanged for back up reinforcers.

Aversive Procedures

In the early days of behavior therapy, aversive procedures were commonly used. In aversion therapy, undesirable target behaviors are systematically followed by an aversive consequence, e.g., electric shocks. Clients seeking treatment for deviant sexual interests were, for example, treated with a paradigm where the deviant stimulus (e.g., pictures of fetish object) was accompanied repeatedly by the delivery of a shock. Such aversive procedures are not commonly used today, partly for ethical reasons, but also because these techniques were found to achieve a suppression of the unwanted response rather than its elimination. However, covert aversion (where the unpleasant consequences of an undesirable behavior are presented through powerful imagery) is used with some success. Real physical aversion is still used sometimes to control self-injurious acts in clients with severe problem behaviors.

Extinction

The most effective technique for reducing and/or eliminating an undesirable behavior is to eliminate the reinforcement that follows that behavior. If this can be done systematically, then the behavior gets effectively extinguished. For example, a child's frequent tantrums may be reinforced by the parental attention that such behavior elicits, and the withholding of this reinforcement can lead to the extinction of this behavior. However, sometimes the reinforcer maintaining the target behavior cannot be identified. A further difficulty is that implementation of a treatment program such that the problem behavior is not even occasionally reinforced is often difficult in practice.

Time Out

Time out (short for time out from positive reinforcement) is the temporary withdrawal of a client's (usually a child's) access to positive reinforcers immediately following the performance of the target maladaptive behavior. In child behavior problems (e.g., hitting others, disruptive shouting), the child is taken to a bland time-out area for a limited period of time, following the undesirable behavior.

Practice of Behavior Therapy

In clinical practice, behavioral techniques are used, sometimes in combination, after a careful analysis of the problem. Such detailed behavioral analysis is a necessary first step before therapy is undertaken. While simple, uncomplicated clinical problems may need only simple and straightforward therapy programs, many clinical cases in real life present complex problems that may require the imaginative use of several behavioral techniques, concurrently or sequentially. At each step, a careful analysis is made of the outcome of the intervention and, if necessary, the program is revised. This experimental, or hypothesis-testing, approach is a major feature of the behavioral approach in its application.

In many instances, the behavioral techniques may need to be combined with cognitive techniques. It was noted in an earlier section that the term cognitive behavior therapy is used by many practitioners for this approach. This approach remains essentially within the broad framework of behavior therapy,

but there is emphasis on acknowledging the significance of cognitions. Cognitive techniques are added to the behavioral ones as needed. In the treatment of panic attacks, for example, the behavioral technique of graded exposure to identified panic-provoking situations is combined profitably with helping the client to identify any faulty cognitions (e.g., "My heart is beating fast, this means I may collapse") and providing evidence that these are unfounded.

Conclusions

Behavior therapy has come a long way since its tentative beginnings in the early decades of this century. It is a well-developed, versatile approach to the treatment of a wide range of behavioral problems, and there is much empirical evidence for the efficacy of its various therapeutic techniques. Some of these techniques are also widely used in helping modify the behavior of nonclinical subjects, e.g., in improving classroom behavior. As an approach to the modification of human behavior, behavior therapy remains well grounded in experimental psychology, especially learning theory. Its emphasis on the careful observation and assessment of problems, defining target behaviors, quantification and measurement, and rigorous outcome evaluation makes it a robust scientific approach.

Behavioral Responses to Stress
Interactions between Behavioral and Physiological
Components of the Stress Response
Behavioral Sources of Stress

Glossary

<i>Appetitive stimulus</i>	A stimulus that induces approach and exploratory responses.
<i>Aversive stimulus</i>	A stimulus that induces avoidance and escape responses.
<i>Behavioral sequence</i>	A succession of appetitive and consummatory components. The appetitive sequence enables the subject to approach the goal object. Upon reaching the goal, appetitive behavior normally ceases and gives way to consummatory behavior that enables the subject to appropriate its goal.

Behavioral Responses to Stress

The stress response was initially described in the context of catastrophic events such as hemorrhage, surgical injury, burns, septic shock, and intoxications. These events cause a reflex-like response that is non-specific and depends on the importance of the deviation from homeostasis. However, more common stressors such as daily life events do not act this way. The response depends on the evaluation by the subject of the potential threat these factors represent. The transactional model of stress is therefore more appropriate than the stimulus–response of stress to describe what is occurring. Novelty, uncertainty, and the absence or loss of control are important dimensions in the evaluation process. An emotional response occurs if the event is recognized as discrepant, and it involves both physiological and behavioral adjustments.

Novelty occurs when the situation contains no or very few familiar elements. Subjects exposed to novelty explore the situation in order to identify potential sources of danger that need to be avoided and potentially interesting objects that can be safely approached.

When novelty is too intense, fear predominates over exploration, and escape attempts replace investigatory behavior. Uncertainty refers to the inability of predicting what is going to happen when the subject is exposed to an aversive or a potentially rewarding situation. In many cases, harmful or rewarding events do not happen all of a sudden. They are preceded by warning signals that can be used to predict their occurrence, via a process of classical (or Pavlovian) conditioning. A tone that occurs before a painful electric shock becomes a fear signal. Inversely, a bell that rings only when there is no electric shock is a safety signal. In an uncertain situation, the subject tries to find regularities in the succession of events to which he or she is exposed, so as to make the situation more predictable. The behavioral response to a fear signal is an anticipatory response that helps the individual to protect him- or herself from the danger. The response to a safety signal is a decrease in the tension and/or anxiety induced by the possible occurrence of the harmful situation. Behavioral responses to a fear signal depend on the subject's proximity to the danger. When the subject is directly in contact with an uncontrollable threat, he or she usually tries to move away from the danger (active avoidance). When the subject is at a close distance from the danger and cannot move away, he or she usually refrains from getting in contact with it (passive avoidance). This response is associated with immobility and freezing.

When the situation is rewarding rather than aversive, events that regularly precede the occurrence of the reward become positive conditioned stimuli or secondary reinforcers. They induce the development of conditioned behavioral responses that involve approach and other appetitive components of the normal behavioral response to the reward. If a secondary reinforcer is no longer followed by the occurrence of the expected reward, it induces a state of frustration that is characterized by agitation, aggression, and other displacement activities (see below).

In situations that involve physical contact with congeners, behavioral responses to stress form part of the agonistic repertoire. Agonistic behavior refers to the complex of aggression, threat, appeasement, and avoidance behaviors that occurs during encounters between members of the same species. Attack is usually a highly ritualized behavior when it occurs in property-protective fights. The offender attacks its opponent at very specific parts of the body, such as the neck in rats, whereas the defender tries to protect these targets from bites. When defeated, the defender

adopts a submissive posture, exposing to the attacker more vulnerable body sites. Submission usually puts an end to the fight.

Confronted with a potentially harmful situation, the subject usually tries to do something in order to avoid the danger. Coping refers to the efforts undertaken to resolve the situation. Active and passive avoidance responses are examples of coping responses. Behavioral manifestations of coping vary according to the situation and the way the threat can be controlled. In laboratory animals, for instance, coping is typically studied by enabling the subjects to escape or avoid painful electric shocks when they emit a specific response such as a lever press, a wheel turn, or a move from one compartment to the other in a two-compartment cage. While animals in the escape/avoidance group are permitted to terminate electric shocks or delay their occurrence, animals in another group serve as yoked controls since they receive the same electric shocks as the previous animals, but their behavioral response has no effect on the occurrence and duration of electric shocks. As a further control, other animals are placed in the same apparatus as the animals in the other two groups, but they are never exposed to electric shocks. Controllability can also be studied in human subjects by asking them to press a button, usually to terminate an intense noise. As in the animal experiment, the yoked group has no control over the noise.

Helplessness refers to an individual's inability to control the situation when he or she has the opportunity to do so. When this happens after a previous experience of uncontrollable stress, it is referred to as learned helplessness. Learned helplessness has cognitive, motivational, and emotional components.

Coping attempts can be classified according to the strategy that is employed to confront the situation. Active coping refers to all ways of dealing behaviorally directly with the situation, e.g., avoidance or attack. In human subjects, active coping can be cognitive (logical analysis and positive reappraisal) or behavioral. The latter case includes seeking guidance and support and taking concrete actions to deal directly with the situation or its aftermath. In an aversive context, cognitive coping comprises intrapsychic processes aimed at denying or minimizing the seriousness of the situation or its consequences, as well as accepting the situation as it is. Behavioral coping includes seeking alternative strategies to directly confronting the problem.

In general, active coping enables the subject to deal directly with the problem and is therefore characteristic of problem-oriented coping. In cases in which the problem cannot be directly dealt with, it is often preferable to engage in passive coping that focuses mainly on managing the emotions associated with it

(emotion-oriented coping). In the case of passive coping, the behavioral activities that are normally elicited by the stimuli present in the situation are redirected toward more easily accessible targets. A typical example is the redirected aggression that develops toward a subordinate when an animal in a social group is attacked by the dominant member of the group. Whereas redirected activities belong to the same behavioral repertoire as the thwarted behavioral activity, displacement activities belong to a different behavioral repertoire. This is the case for aggressive behavior that is targeted toward peers or other objects in the environment in an animal that does not get the food it was expecting. A well-studied form of displacement activity is schedule-induced behavior. Schedule-induced behaviors, also known as adjunctive activities, typically occur when hungry animals are exposed to intermittent food rewards, delivered in very small amounts independently of the animals' behavior. Immediately after animals have eaten their allocated food, they vigorously engage in other activities depending on what is available in the situation. They drink exaggerated amounts of water if a drinking tube is accessible, attack a congener when present, or gnaw a piece of wood if available. To qualify as an adjunctive behavior, the behavioral activity must occur as an adjunct to the reinforcement schedule, not be directly involved in, or maintained by, the reinforcement contingency, and be persistent and excessive. Independently of the object toward which they are directed, adjunctive behaviors occur at a maximum rate immediately after the reinforcement and decrease in probability when food deprivation is alleviated.

Interactions between Behavioral and Physiological Components of the Stress Response

Compared to uncertainty and lack of control, predictability and controllability have deactivating effects on the physiological arousal evoked by the stress situation. In social conflict situations, activation of stress hormones is in general more pronounced in subordinate animals that behave defensively or passively than in offensive animals that remain active and become dominant. However, the social role is more important than the social status since dominance is associated with a reduced arousal response only when dominant animals are recognized as such by their peers and do not need to reaffirm their status each time they are challenged by subdominant animals.

Schedule-induced polydipsia is associated with lowered plasma levels of stress hormones. This property is shared by other motor activities that involve

sensory overloading from the mouth and tongue (e.g., licking or chewing) or the limbs (e.g., pacing). The de-arousal properties of coping behavior are not always that clear. Coping attempts are associated with increased activation of the sympathetic nervous system, and they result in decreased physiological activation only when they have been successful and the threat is over.

The relationship between behavioral and physiological components of the stress responses is not unidirectional, with behavior influencing physiological responses, but truly bidirectional in the sense that the likelihood of a given behavioral response is dependent on the subject's initial physiology. Individuals with high activity of the sympathetic-adrenal-medullary axis are more likely to try to cope in an active way with a threat than individuals with a low activity of the sympathetic-adrenal-medullary axis. Inversely, individuals with a relatively higher activity of the hypothalamic-pituitary-adrenal axis are more likely to resign and display helplessness than individuals with a normal or a lower activity of this axis.

Behavioral Sources of Stress

Most psychobiological theories of stress emphasize the previously described bidirectional relationships between the behavioral and physiological components of stress in response to stressors. However, they do not necessarily account for the powerful influence of the subject's own behavior on the probability of occurrence of the stressful situation itself.

A typical example for understanding this point is represented by the type A behavior pattern (TABP). TABP is defined as an action-emotion complex that individuals use to confront challenges. The complex involves behavioral dispositions such as aggressiveness, competitiveness, and impatience; specific behaviors such as muscle tenseness, alertness, rapid and emphatic vocal stylistics, and accelerated pace of activities; and emotional responses such as irritation, covert hostility, and above-average potential for anger. Type B individuals are characterized by the relative absence of type A behaviors and confront every challenge with placid nonchalance. Type A individuals have a higher risk of developing coronary heart disease than type B individuals. The deleterious effects of type A behavior appear to be associated with a higher physiological reactivity to external demands, especially when there

are elements of competition. These findings corroborate the previously mentioned influences of behavioral factors on the physiological response to stress. In accordance with the bidirectional nature of hormone-behavior relationships, type A behavior does not occur at will. It is determined at least in part by biological factors and autonomic hyperactivity. All this makes type A behavior a typical psychobiological construct. However, this concept is not sufficient to account for what happens in the real world. Type A individuals actually create their own problems by putting themselves in situations of competition and taking all steps to transform the events they are confronted with in challenges that need to be met in a more hostile way than their peers would be inclined to do.

A similar situation occurs in sensation-seeking individuals. There is evidence that subjects with this personality trait display enhanced responses to novelty and danger. The probability for a given individual to be a sensation seeker is determined by innate and experiential factors. However, what is characteristic of sensation seekers is their strong preference for sensation-inducing situations rather than their increased response to such situations. In sum, individuals are not passively exposed to stress; they actually create their own stress by the way they behave and perceive their environment.

Glossary

<i>Akathisia</i>	Motor restlessness, characterized by the inability to sit still, often occurring as a result of ingesting medications that block dopamine receptors.
<i>Allosteric modulator</i>	A molecule that binds to a protein at a regulatory site, spatially distinct from the primary site of activation. Allosteric modulators alter protein activity by modifying the affinity of the principal molecule to the primary site of activation.
<i>Anterograde amnesia</i>	The inability to form new memories for a limited period of time following a specified event, even though overall consciousness is preserved.
<i>Cognitive-behavioral therapy (CBT)</i>	A type of psychotherapy in which the therapist teaches the patient to restructure his or her maladaptive thoughts (i.e., cognitions) in order to improve overall functioning (i.e., behavior).
<i>Glucuronide conjugation</i>	A form of metabolism, usually in the liver, involving the attachment of glucuronic acid to another molecule, thereby producing a derivative that is more easily eliminated from the body through urine excretion.
<i>Hyperpolarization</i>	The reduction of the electric potential (or voltage) of a neuron to a level below that of the normal resting state. This opposes neuronal excitation by inhibiting or slowing action potential propagation (the flow of positive charge along neurons).

Hypnotic

Ligand-gated ion channel

Acting to induce sleep or drowsiness.

A transmembrane ion channel in which the flow of ions through the channel is increased by the binding of an activating molecule (termed a ligand), such as GABA to the GABA_A receptor.

Limbic system

A circuit of interconnected brain structures that controls and influences emotional behavior and perceptions.

Retrograde amnesia

The loss of memories that have already been formed prior to the inciting event.

Somatic

Pertaining to the body; physical or corporeal. In psychiatry, somatic usually connotes a physical or physiological manifestation of mental anguish.

History and Introduction

Benzodiazepines (BZs) surfaced for broad clinical use in the 1960s as potent anxiolytics (anti-anxiety medications). Prior to this period, barbiturates and meprobamate had been favorites in treating anxiety, but they had variable clinical efficacy and substantial safety risks. The introduction of the BZs, whose safety-efficacy profiles exhibited marked superiority to their predecessors, led to substantial changes in medication-prescribing practices. By 1977, diazepam (brand name, Valium) became the single most commonly prescribed medication in the United States. Then, reports of BZ abuse and addiction spread, invoking widespread concern over their use. The 1980s and 1990s witnessed a decline in BZ popularity coupled with exaggerated beliefs about their side effects and habit-forming potential. In more recent years, however, the accumulation of extensive clinical research has begun to reverse prior misconceptions. This synopsis reviews the basic and clinical pharmacology of BZs, as well as current understandings of their efficacy, safety, and liabilities as anxiolytics.

Basic Pharmacology

The core structure of clinically relevant BZs consists of a benzene ring joined to a seven-member 1,4-diazepine ring (see [Figure 1](#)). BZs bind to GABA_A receptors on the extracellular surface of neurons in the brain. The pentameric (or five-subunit) GABA_A receptor complex is a ligand-activated chloride channel. The binding of the endogenous ligand GABA (γ-aminobutyric acid) to the GABA_A receptor leads to channel opening, allowing chloride ions to flow passively into neurons. The chloride ion flow through

GABA_A channels induces neuronal hyperpolarization. Hyperpolarization then slows nerve transmission by reducing the probability of action potential propagation along neuronal membranes. This physiological action is essential in prohibiting uncontrollable states of brain activation.

BZs exert their therapeutic effects through a mechanism of allosteric modulation. That is, they bind to the GABA_A receptor complex at a location that is distinct from the GABA binding site and facilitate increased chloride ion flow through the channel by enhancing GABA binding (see [Figure 2](#)). Alone, BZs are unable to open GABA_A ligand-gated channels to

Figure 1 Core structure of 1,4-benzodiazepines. Numbered R groups designate positions of variation that distinguish the individual BZs (see also [Figure 3](#)). Note that 1,4 refers to the position of two nitrogen (or di-aza) atoms.

effect intracellular chloride entry. Such restricted modulatory capacity of BZs contrasts with the direct channel-opening properties of barbiturates and defines the comparative safety of BZs. When taken in overdose, barbiturates are capable of producing massive neuronal inhibition that can lead to respiratory depression, coma, and eventually death. In contrast, maximal BZ effects are limited by the physiological availability of GABA, reducing their potential of generating excessive neuronal inhibition. Although oversedation and some respiratory depression can occur, lethal consequences from BZ overdoses are rare. Lethal inhibitory effects usually require high combination doses of BZs with additional sedatives (e.g., alcohol) to occur in healthy individuals.

Clinical Pharmacology

BZs cause a spectrum of central nervous system (CNS) inhibitory effects: sedation, dampening of memory and cognitive functioning, interruption of seizures, muscle relaxation, and reduction of anxiety. Among the BZs, distinct modes of action are imparted by their individual rates of absorption, delivery to the brain, metabolism, and elimination. For example, diazepam

Figure 2 Increased activation of the GABA_A receptor complex by BZs. a, Before BZ binding; b, after BZ binding. The pentameric (or five-subunit) GABA_A ligand-gated channel, consisting of 2 β , 2 α , and 1 γ subunits, is shown conducting chloride intracellularly following GABA binding to the α - β interface. BZ binding at the α - γ interface results in allosteric enhancement of GABA-mediated channel opening, illustrated by increased chloride conductance. In the absence of GABA, BZs are unable to activate the channel, conferring safety in an overdose. In contrast, barbiturates directly activate the receptor complex and are consequently much more dangerous in an overdose.

Figure 3 Examples of 1,4-benzodiazepine structures and subclasses. a, 2-Keto; b, 3-hydroxy; c, triazolo.

is very lipid-soluble (lipophilic), rapidly absorbed, and easily distributed into the brain with a quick onset of action. BZs with reduced lipophilicity, lorazepam and clonazepam, are more slowly delivered to their target sites in the brain thereby inducing more gradual onset of CNS effects (particularly with clonazepam).

In addition to such individual differences, categorical features of BZs can also be appreciated by grouping them into three major subclasses (see [Figure 3](#)), particularly regarding their metabolic properties. The metabolism of 2-keto BZs involves slow oxidation in the liver. Also, metabolic products in this subclass are usually active, frequently more active than the parent compounds. As a result, 2-keto BZs exhibit appreciably long-lasting clinical effects. In fact, 50% of their activity (or one half-life) remains between 30 and 60 h after initial dosing. BZs within the 3-hydroxy subclass also undergo liver metabolism, but the process is more rapid (via glucuronide conjugation rather than oxidation), with the inactivation of the parent

compounds. Consequently, 3-hydroxy BZs exhibit shorter half-lives (~ 8 –14 h) than their 2-keto counterparts. Similar to the 2-keto agents, triazolo BZs are also oxidatively metabolized. Yet triazolo metabolites are much less active than the parent compounds. Hence, the overall half-lives of agents within the triazolo subclass range from ~ 3 to 12 h.

Choosing a BZ for any particular clinical indication involves a consideration of various pharmacokinetic factors: desired speed of onset, importance of sustained anxiolytic action, and the influence of a patient's age or other medications on BZ metabolism and physiological accumulation. Consequently, optimal selection and proper dosing of BZs involves patient-specific tailoring.

Clinical Uses

Psychiatric Indications

Relative to other classes of psychiatric medications, BZs have established a remarkably versatile clinical

utility. As a class, BZs are used to treat various stress disorders, either alone or in combination with antidepressants. Most commonly, these include panic disorder and social and generalized anxiety disorders. Somewhat shorter-acting BZs, such as temazepam and triazolam, are frequently prescribed as hypnotics, with insomnia representing a major clinical indication for these compounds.

In combination with other agents, BZs can be quite useful in calming agitation states seen in psychosis and mania and in expediting the speed of antidepressant response in major depression. Symptoms of anxiety and sleep disturbances are observed in many psychiatric conditions, particularly in acute phases of illness, accounting for the benefits that BZs provide in such diverse settings.

Medical Applications

In addition to their uses in psychiatric conditions, BZs are relied on in medical practice to diminish a number of physical symptoms. These include muscle spasms, gastrointestinal cramping, and akathisia (a form of restlessness). Acute and chronic seizures have been treated by diazepam and clonazepam, respectively, with long-standing proven efficacy. These two agents, in addition to lorazepam and chlordiazepoxide, are also commonly used to prevent the symptomatic onset of alcohol withdrawal. With such a range of efficacy in mental and physical conditions, BZs are often touted as the most effective medications available for anxiety states that present with somatic (i.e., physical) symptoms.

Lack of Benefit in Posttraumatic Stress Disorder

Essentially, where there is intense fear or distress, BZs are powerfully and effectively calming. Perhaps the only glaring exception to this rule lies in the treatment of posttraumatic stress disorder (PTSD), a disorder of excessive and prolonged anxiety, often lifelong, following exposure to a severe traumatizing event. In limited studies, BZs have been unable to improve sleep or nightmares in PTSD and have even appeared to worsen the risk of developing chronic PTSD following trauma.

Given the combined presence of anxiety and insomnia in PTSD, it is surprising that BZ efficacy has not extended to this condition. One possible explanation may relate to the neurobiology of PTSD as a powerfully intensified and easily arousable emotional circuit. In PTSD patients, this pathological circuit appears to be so hard-wired in the brain as to be unusually refractory to the calming effects of BZs. In addition, the suppression of this circuit may be uniquely dependent on maximal cognitive functioning,

which can be impaired by acute BZ treatment. In this model, higher cognitive and reasoning abilities are required to stave off unwanted emotional arousal of traumatic memories. Consistent with this conceptualization, intelligence and higher cognitive functioning have been found to reduce the risk of developing PTSD. If such a theory proves valid, short-term trials with BZs are not expected to be beneficial in PTSD, as is generally supported by the current clinical literature. Larger studies designed to comprehensively examine BZ effects in this disorder, however, have not been conducted.

Acute versus Chronic Utility

BZs are usually most effective in relieving acute distress rather than chronic anxiety or despair. Their efficacy in major depressive disorder has been optimally demonstrated during acutely severe, often suicidal, phases of the illness. They are otherwise inferior, or provide no additional benefit, to antidepressants in treating chronic depression. BZs are also not commonly effective in obsessive-compulsive disorder (a stubbornly chronic condition).

However, data are conflicting regarding long-term BZ use. Agents such as alprazolam and clonazepam demonstrate reductions in the frequency of recurrent panic attacks (with or without antidepressant combinations). Also, clonazepam has shown limited, but robust, effects in chronic social anxiety. Hence, the clinical evidence of BZ efficacy in chronic psychiatric disorders is mixed.

Combination of Benzodiazepines with Psychotherapy

BZs can be combined with some forms of psychotherapy, or vice versa, to enhance overall treatment effects when conducted in the proper context. Most studies to date have examined the use of BZs with CBT. CBT produces robust and persisting benefits in a number of anxiety disorders by providing patients with the psychological skills to endure exposure to stressful conditions. However, successful CBT implementation requires several weeks to months of treatment. Some clinical trials have indicated that the addition of BZs to CBT can accelerate the therapeutic process by facilitating fear extinction. While on BZs, CBT patients are capable of exposing themselves more quickly to previously unbearable stress. Yet the subsequent discontinuation of BZs in the course of psychotherapy can reignite prior anxiety, providing no added benefit overall. From these findings, fear extinction appears to be somewhat context-dependent. In other words, severe anxiety may recur easily when

the context of its remedy is altered (e.g., on removal of BZs). Accordingly, in cases in which BZs do hasten the progress of CBT or another psychotherapeutic modality, their discontinuation should be conducted gradually with continued psychotherapy to optimize patient adaptation to newly unmasked stressors.

Conversely, the addition of CBT to BZs reveals consistently successful results in promoting medication discontinuation and can be a particularly useful strategy in cases in which tapering patients off BZs is desired and challenging.

Common Adverse Effects

Overall

The side effects from the acute administration of BZs primarily include sedation, cognitive impairments, ataxia (imbalance), weakness, and motor incoordination. However, many of the acute BZ side effects do not appear to be problematic during long-term use. The most commonly observed side effect, sedation, is dose-dependent and can be well managed with dose reduction until tolerance develops within a few weeks.

Considerations in Elderly

Risks of daytime sedation and ataxia are more worrisome in elderly patients, due to the potential for falls and dire consequences, such as hip fractures. Consequently, a careful consideration of BZ dosing, half-life, and metabolism is given to elderly patients on these medications. The oxidative metabolism of BZs is more likely to be sluggish in the elderly and may produce unpredictably sustained action and the potential for toxic accumulation. BZs with longer half-lives or whose metabolism is impaired by concomitant use of other medications may also produce dangerous effects. The more easily metabolized 3-hydroxy BZs (such as temazepam, oxazepam, and lorazepam), or agents with shorter half-lives, are considered relatively safer options in elderly patients. However, factors of half-life and metabolism are not sufficiently predictive of adverse events. Hence, close monitoring of patient functioning is required when using BZs to address anxiety and/or insomnia in the elderly.

Effects on Cognition

Acute Effects

As with their sedating properties, BZs administered acutely can slow overall cognitive functioning. Impairments are observed in visuomotor (or hand-eye) coordination, attention, working memory (e.g., in following directions), and new memory formation (producing anterograde amnesia).

Chronic Effects

The impact of chronic BZ use on cognitive functioning is much more controversial. Some reviews have illustrated evidence of broad-based cognitive impairments. These retrospective analyses, however, have been unable to control adequately for the burden of underlying psychiatric disease on mental acuity. Recent prospective studies comparing anxious patients with and without chronic BZ treatment do not reveal distinct BZ-induced cognitive deficits, except possibly in the realm of verbal episodic memory.

Behavioral Dyscontrol Reactions

Unexpectedly intense behavioral responses to BZs occur very infrequently (with < 1% incidence). Sensationalized reporting of these effects, however, has produced disproportionate awareness and concern among physicians. Often termed paradoxical, disinhibitory, or dyscontrol reactions, they encompass such symptoms as talkativeness, agitation, irritability, confusion, unseemliness, aggression, and loss of impulse control with potentially violent consequences. When they occur, the pathophysiology is not understood, but reversal by flumazenil (a BZ antagonist) can be effective and supports a BZ causal link to these phenomena. Children, elderly, and alcohol-dependent patients appear to be at greater risk.

Dyscontrol reactions may stem from an acute confusional or disoriented state, such as delirium. If so, individuals with severe illness or impaired cognition (who are at greater risk for the development of delirium) may also be expected to be more vulnerable to the unlikely development of these bizarre, paradoxical BZ reactions.

Physical Dependence and Withdrawal

Debate about chronic clinical use of BZs stems, in part, from their propensity to induce physical dependence (herein defined as the appearance of unpleasant physiological symptoms on sudden BZ withdrawal). Sudden withdrawal from BZs can produce jitteriness, sweating, clamminess, nausea, seizures (less commonly), and the reappearance of pre-BZ anxiety. These symptoms appear within 2–7 days after sudden BZ discontinuation, depending on the half-life of the agent involved. Similarly, rebound refers to the appearance of anxiety symptoms in excess of the pre-BZ state, sometimes seen with the sudden cessation of short-acting BZs (e.g., alprazolam) that eliminate quickly from the bloodstream. Long-acting BZs such as the 2-keto agents (e.g., diazepam and clonazepam) rarely produce rebound and generally tend to produce

fewer withdrawal symptoms than their shorter-acting counterparts (although seizures can still occur).

The daily use of BZs in human studies reveals that physical dependence begins to form after 6–8 weeks, raising ethical objections to their initiation in the treatment of anxiety disorders. In comparison, many other psychotropic agents (including selective serotonin reuptake inhibitors, SSRIs) induce withdrawal symptoms on cessation, leading to physiological dependence. Some experts suggest, then, that these effects from BZs should not be overemphasized when considering poorly treated anxiety as the alternative. Nevertheless, most psychiatrists agree that BZs often necessitate uniquely prolonged and involved dose tapering prior to their discontinuation. This can be more effectively accomplished by converting patients from short-acting BZs (e.g., alprazolam) to long-acting equivalents (e.g., diazepam) in the process of dose tapering (and/or the initiation of CBT, as previously described).

Abuse Liability

Animal versus Human Findings

Much debate has surrounded the addictive potential of BZs. Findings in primate and other animal studies indicate that these medications reinforce self-administration, a preclinical model for abuse liability and a basis for their controlled prescription regulation. Within the class, BZs with rapid onset (e.g., diazepam) and/or short action (e.g., alprazolam and triazolam) are considered more liable to reinforce drug-seeking behavior. However, following initial isolated reports of addiction in humans in the early 1980s, subsequent epidemiological studies have not found this to be a significant problem overall (in contrast to opiate or barbiturate abuse). Approximately 15% of BZ users continue their BZs beyond 1 year, with less than 2% of long-term users exhibiting escalating dosages and/or multiple prescriptions. These low percentages support the notion that early physical dependence is manageable and does not frequently lead to long-term dependence or tolerance to the clinical benefits of BZs. The findings also suggest that the vast majority of patients do not seek BZs for euphoric effects or illicit use.

Vulnerable Patient Populations

The patients who do tend to abuse BZs are usually those with alcohol- or other drug-abuse disorders. In these settings, BZs are abused secondarily to augment the mind-altering effects of other addictive substances. This can be particularly problematic in the clinical setting of alcohol withdrawal when BZ is used as a substitute in alcohol detoxification

(withdrawal). Loading and short-term maintenance with BZs remain the mainstay of ensuring safety during alcohol withdrawal (by preventing withdrawal seizures and fluctuating blood pressures). Yet patients who relapse on alcohol during BZ maintenance may have lethal consequences from the combination. Notwithstanding the latter scenario, BZs can be administered generally without addictive potential in humans, particularly once substance abuse is reassuringly ruled out.

Tolerance and GABA_A Subunit Specificity

Differential Effects

Physiological tolerance refers to the lessening of a drug's effect over time. As previously described, tolerance to the anxiolytic properties of BZs is not commonly observed in long-term use (illustrated by the lack of dose-escalation requirements in routinely treated anxiety disorders). In contrast, the early clinical effects of sedation, ataxia, and cognitive impairment (such as inattention) tend to resolve over time.

Molecular Models

Intensive molecular research efforts have attempted to explain such differential tolerance to BZs. These efforts have uncovered a remarkable diversity of α -, β -, and γ -subunit isoforms making up GABA_A channels throughout the brain (see [Figure 2](#) for GABA_A structure). Of note, $\alpha 1$ subunits are distributed widely and implicated heavily in transmuting the amnestic and sedative effects of BZs, whereas the anxiolytic effects seem to be attributed to the $\alpha 2$ and $\alpha 3$ subunits, whose distribution is concentrated more in the limbic (emotional) brain centers. Observations that $\alpha 1$ (but not $\alpha 2$ and $\alpha 3$) subunits downregulate in response to chronic BZ treatment correlate with clinical findings of tolerance to their amnestic and sedative (but not anxiolytic) effects over time. Functional differentiation of these subunits has also led to the development and clinical availability of $\alpha 1$ -selective nonbenzodiazepine analogs (including zolpidem and zaleplon) for the treatment of insomnia. These $\alpha 1$ -selective hypnotics appear to impart reduced tolerance to their sedative benefits compared with traditional BZs for reasons that are not yet entirely clear.

Future Directions and Conclusion

Our burgeoning molecular understanding of BZ-related tolerance and subunit-specific clinical effects has engendered future hopes of developing powerful anxiolytics that lack sedative, ataxic, and cognitive liabilities. In particular, many pharmaceutical

companies have attempted to produce BZ analogs whose pharmacological action is selective to $\alpha 2$ and $\alpha 3$, but not $\alpha 1$, subunits. A few candidates remain in this space with promising early findings. Yet the engineering of such agents with subunit-selective and pure anxiolytic efficacy has been considerably challenging. Theories about subunit-selective efficacy are also evolving with these efforts and may ultimately prove to be even more complex and interesting than our current understanding.

Until then, BZs remain a time-tested gold standard in the pharmacological treatment of anxiety disorders, particularly for states of acute distress but also for some forms of chronic illness. In summary, the fundamental pharmacology of BZs, as allosteric modulators of the GABA_A receptor complex, delineates a unique balance of safety and efficacy in the therapeutic pursuit of anxiety-free homeostasis.

Treatment

Glossary

<i>Bereavement</i>	The state or fact of being bereaved, suffering the death of a loved one; the loss of a loved one by death.
<i>Disorders</i>	So disturb the regular or normal functions of; an abnormal physical or mental condition: ailment.
<i>Grief</i>	Deep and poignant distress caused by loss, a cause of such suffering.
<i>Mourning</i>	The act of sorrowing; a period of time during which signs of grief are shown.
<i>Outcome</i>	Something that follows as a result or consequence.
<i>Complicated grief</i>	A disordered psychic or behavioral state resulting from a deep and poignant distress caused by or as if by bereavement.

Introduction

Although no-one would argue that the loss by death of someone close is a significant life event, the degree of adversity that the death brings to the individual is variable. The field is just beginning to identify and study people who are most severely affected. In studying bereavement, most investigators have used entry in widowhood as the model, although the response to the death of a child is probably more stressful. This article will concentrate on research on bereavement which by definition is a reaction of a person to loss by death. Other terms in the literature which should not be confused with bereavement are grief, which is the emotional and psychological reaction to any loss but not limited to death, and mourning, which is the

social expression of bereavement or grief, frequently formalized by custom or religion.

At this point there have been numerous longitudinal follow-up studies of people who have been recently bereaved. The majority deal with the widowed although there are excellent studies of children who have lost a parent. Despite the fact that the mode of selection, response rate, gender, age group, time since the death to the first interview, comparison groups, and the selection of instruments and outcome measures differ greatly from study to study, the similarities of outcome outweigh the differences. Our own data highlight the major outcomes, although important additional findings have been identified and there are still areas of controversy.

Bereavement is the ideal condition to study the effect of stress on the organism. It is not species specific so it can be defined identically across species and generations of species. It is a real event, not artificial, imagined, or devised, it is datable, it occurs in present time so it can be studied immediately, not retrospectively, and even prospectively. Finally, the significance of the event would not be disputed. Before reviewing the morbidity and mortality associated with this clear-cut, easily defined stress, it is important to emphasize that by far the most usual outcome following this experience is numbness for a very brief period, depression for a variable time, and then recovery. Recovery is the return of the individual to the level of functioning that he or she had established before the death and/or a change in a positive direction. In some cases this takes months, in others, up to 2 years or more. This is described by Lund et al. (1993: 24) in older adults. Only 10–15% of individuals develop chronic depression, with even fewer experiencing complicated grief. In studying the biology of this particular stress, whole populations have to be studied so that we define the usual, natural outcomes as well as the abnormal responses.

Depressive Symptoms and Course

In studying relatives' reactions to the loss of a significant person, we collected data on three different samples. The first sample was a group of 40 bereaved relatives of people who had died at a general hospital in St. Louis, United States. The second was a sample of widows and widowers chosen from the death certificates and seen at 1, 4, and 13 months after the deaths of their spouses. The third sample was a consecutive series of young (<45 years old) widowed people also seen within 1 month after the death and

again at 1 year. The last two samples were matched through the voter registry with married people of the same age and sex who had not had first degree relatives die, and who were also followed prospectively to ascertain their morbidity and mortality. The findings are exemplified in Table 1 which displays the depressive symptoms that were endorsed at 1 and 13 months. In the first month, a large majority of the sample experienced depressed mood; anorexia and beginning weight loss; insomnia that was initial, middle, and terminal; marked crying; some fatigue and loss of interest in their surroundings, but not necessarily the people around them; restlessness; and guilt. The guilt that these people expressed was different to the guilt seen in depressed patients. For the most part it was guilt of omission surrounding either the terminal illness or the death. Irritability was common but overt anger was uncommon. Suicidal thoughts and ideas were rare. When they did occur they occurred in younger men after the death of a wife or in men and

women after the death of a child. Hallucinations were not uncommon. Many widows and widowers, when asked, admitted that they had felt touched by their dead spouse or had heard his or her voice, had seen his or her vision or had smelled his or her presence. The misidentification of their dead spouses in a crowd was extremely common.

We matched some of our subjects with well-studied hospitalized depressed patients and found, as Freud suggested, symptoms such as feeling hopeless, worthless, being a burden, psychomotor retardation, wishing to be dead, and thinking of suicide differentiated the depressed from the bereaved.

By the end of the first year the somatic symptoms of depression had remarkably improved. Low mood (usually associated with specific events or holidays), restlessness, and poor sleep continued. The few psychological symptoms of depression, although rare, resolved less easily. In our studies, the symptoms were as frequent in men as in women, in people who had lost a spouse suddenly or after a lingering death, in people who had good or bad marriages, and people who were religious or nonreligious. Young people were more likely to have a severer immediate reaction, but by 1 year their outcome was similar. There was no relationship between financial status and outcome.

As Table 2 shows, when the frequency of depressive symptoms were compared to the community controls, all symptoms were more common among the bereaved.

When depressive symptoms reported at 13 months were examined by those with symptoms for the entire year and those who had just developed them, the percent who had new symptoms was similar to those reported by the controls who had had no deaths (Table 3). Those who were disturbed early were more likely to be disturbed later. Delayed grief, like delayed posttraumatic stress disorder (PTSD), may be an interesting ideologic concept but remains unproven. It is also counterintuitive since the usual recognized reaction to a physical or psychological insult is an immediate injury with a gradual resolution. This has been confirmed by others.

Physical Symptoms, Substance Use, and Medical Treatment

We systematically ask about physical symptoms, usually associated with major depression, in both the recently widowed and control subjects (Table 4). In general, physical symptoms were not more frequent in recently bereaved and controls subjects. Nor did they change much over the year. The largest difference was recorded in "other pains" which were mainly in the elderly bereaved and consisted of

arthritic type pains. In our studies, there were no more physicians' visits or hospitalizations in the year following the bereavement. This is controversial.

The most striking finding of this research is illustrated in Table 4. After a significant stress such as bereavement the use of alcohol, tranquilizers, and hypnotics significantly increased. For the most part these were not new users but people who had used them before. Cigarette smoking also increased. The morbidity and mortality of bereavement may be related to these changes in behavior. It also highlights how people behave after significant stress.

In a separate study, we examined 249 psychiatric inpatients and similarly matched hospital controls and found that there were no significant differences between the groups for the loss of a first degree relative or spouse in the 6 months or 1 year prior to admission to the hospital. In each case only 2% reported such a loss in the 6 months and 3 or 4% in the 7–12 months prior to the hospitalization. In the psychiatric patients, the major diagnosis was a mood disorder. There were diagnoses of alcoholism in

both the bereaved psychiatric patients and bereaved hospitalized controls which related to their increased drinking after the death.

Psychiatric Disorders – Depression, Anxiety, and Mania

In our first study of widowhood, 35% of the subjects had a depressive syndrome at 1 month, 25% at 4 months, and 17% at 1 year. Forty-five per cent were depressed at some point during the year and 11% were depressed for the entire year. Adding the second younger sample, 42% were depressed at 1 month and 16% met the criteria at 1 year. Forty-seven per cent were depressed at some time during the year compared to 8% of controls and again, 11% for the entire year. These findings are remarkably similar to those of a study extensively reported by Zisook and Shuchter (1991: 1346; 1993: 157). They identified a large sample of widows and widowers from death certificates and solicited volunteers to be interviewed. The demographics of the final sample were very similar to the first widowed sample reported here.

Berlin-Heidelberg: Spring-Verlag.

They reported that 24% of their sample was depressed at 2 months, 23% at 7 months, 16% at 13 months, and 14% at 25 months. In all of these studies the best predictor of depression at 13 months was depression at 1 month. In the Zisook and Shuchter studies, a past history of depression also predicted depression at 1 year. In our own studies, because we did not have enough depressed patients, it was any psychiatric morbidity prior to the death that predicted depression at 1 year. The other common correlate of depression at 1 year was poor physical health prior to the death of the spouse. So, prior poor physical or mental health predicted poor outcome at 13 months. Although there are methodologic issues in defining both anticipation of a death (e.g., expected versus unexpected) and outcomes (depression, death, remarriage, etc) in our data, unexpected deaths produced more severe immediate responses but the differences disappeared by 13 months, again confirmed by others. The best definitions of unexpected death, is a death in a healthy individual which occurred in less than 2 hours. Using that and comparing it to those bereaved after longer terminal illnesses we found that it has been reported that there was more morbidity especially as measured in physician visits, and long lingering grief symptoms.

In more than one study, about 25% of recently bereaved subjects met criteria for some anxiety disorder immediately following bereavement. More than half, however, had generalized anxiety disorder and that correlated with the severity of the depressive disorder. Others have shown, without clarifying the nature of the anxiety disorder, the major disorders that affect recently bereaved people are depressive disorder alone or concurrent depression and anxiety. New episodes of any anxiety disorder were rare after bereavement. It may be wisest to conclude that these are anxiety symptoms embedded in a depression disorder.

An occasional person, with a bipolar disposition, develops mania following a significant death, probably secondary to the sleep deprivation that the stress induces.

Complicated or Traumatic Bereavement

Lindemann (1944: 24) probably wrote the first papers on bereavement that dealt with prospective observations of 13 bereaved subjects who were hospitalized at Massachusetts General Hospital after the Coconut Grove fire. He combined these observations with those of his own patients who lost a relative during treatment, with relatives whom he saw of patients who died at the hospital, and of relatives of members of the Armed Forces. Although he considered his observations to be of normal grief, many of them were probably related to a pathologic response. More recently, investigators have begun to quantify the abnormal response. Prigerson and colleagues (1995: 616) have developed an inventory of complicated grief and shown it to be related to the severity of depressive symptoms, but with distinct symptoms. Building on earlier inventories such as the Texas Grief Inventory and the Grief Measurement Scale, they took symptoms such as preoccupation with death, crying, searching and yearning for the deceased, disbelief about the death, being stunned, and not accepting the death and added questions about preoccupation with thoughts of the deceased, anger, distrust, detachment, avoidance, replication of symptoms that the deceased experienced, auditory and visual hallucinations, and guilt, loneliness, bitterness, and envy of others who had not lost someone close. Their instrument was shown to be reliable and have criterion validity. Whether it is just defining the most severe depression is not yet clear. Modifying the Grief Measurement Scale in accordance with the above symptoms, Prigerson et al. (1997: 616) looked at a previously ascertained sample that were followed from before the death to until 25 months after the death. They found that if they identified bereaved

at 6 months who scored high on their inventory, at 13 months there was a correlation between high scores and change in smoking and eating, depression, and high systolic blood pressure. At 25 months, these people had an increased risk to develop heart trouble and cancer and more often expressed suicidal ideation as ascertained on a single item. If they tried to separate the sample on complicated grief at 2 months, they could not predict unfavorable outcomes. There are others working on similar instruments, especially in Australia. They measured bereavement phenomena and developed a scale for core bereavement items. This scale also measures images and thoughts around the death, yearning and pining about the death, and some grief symptoms such as sadness, loneliness, longing, tearfulness, and loss of enjoyment. Their inventory was developed using parents of deceased children, bereaved spouses, and bereaved adult children who scored high in descending order on the inventory. However they have not yet correlated the questionnaire with outcome.

Some of the symptoms in all of these inventories are similar to symptoms that occur in PTSD, and it is difficult to justify a new category where the major difference is that in the bereaved, the mood is sadness and loneliness focused on the loss compared to fear or horror in PTSD. It is still an unanswered question. Should we have a diagnosis of complicated bereavement or acknowledge that after certain deaths, most especially those that are sudden and violent, some individuals will develop PTSD which is usually comorbid with major depression? Clearly these investigators are defining an important bereavement response that identifies survivors with a poorer outcome. For other researchers who are studying human reactions to stress, symptoms such as those in the inventory of complicated grief should be identified and studied prospectively. The identification of such a syndrome also makes it possible to study, more specifically, various interventions.

Mortality

More recently the method of study (collecting health data on a large core of men and women and following them prospectively to ascertain point of widowhood and using the Cox hazards regression mode to estimate the effect of bereavement on mortality while controlling for the effects of other covariates), should have greatly improved the validity of the mortality data. Unfortunately, there still are controversies. Three studies have used these methods. De Leon et al. (1993: 519) reported that elderly, young-old (aged 65–74 years), and old-old men (aged > 74 years) showed an increased mortality in the first 6 months of

widowhood. But, because there was an age difference between the future widowed and nonwidowed, when they were age adjusted, the death rate fell to a non-significant level. Among young-old women there was also an increased risk of death in the first 6 months which only decreased slightly after the age adjustment, but enough to make it of borderline significance. The authors suggested that the “true risk period” may be even shorter than 6 months. Schaefer et al. (1995: 1142) also reported that mortality following bereavement was significantly elevated in both men and women after adjusting for age, education, and other predictors of mortality. Here, the highest mortality occurred 7–12 months following the bereavement. Ebrahim et al. (1995: 834) studied 7735 middle-aged men (40–59 years) over 5 years. They included never married, divorced, separated, widowed, and married men and found that there was no increase in mortality in men who became widowed during the follow-up time. There were only 24 men who became widowed in that follow-up period which probably limited the findings. Lusyne et al. (2001: 281) confirmed an excess mortality in the first 6 months of widowhood which was higher for men than women. As others had found, it was highest in the youngest bereaved (<60 years) and dropped with each older group and almost disappeared for the oldest old. There is also a twin study of mortality after spousal bereavement. Without relating whether the twins were mono- or dizygotic, the authors found an increased mortality for young-old (under 70 years) men and women during the first year of bereavement. The death hazard diminished the longer the bereaved were followed. The data were analyzed for smoking status, excessive alcohol consumption, education, body mass, cardiovascular disease, respiratory disease, and other chronic illness and found that these did not affect the relative hazard estimates. Other studies show that remarriage, which is much more likely to occur in men, protects men from death either because the healthier remarry or the remarriage in itself is protective. The death rates of those who remarry are similar to married men of the same age. Taken as a whole, these studies support the fact that there is probably an increased mortality after bereavement in men and women under 70 years of age in the first year.

From these studies there does not seem to be an increased mortality from any one particular cause, such as cancer or cardiovascular disease. Other studies, however, have shown an increase in suicide after a bereavement, although when looking at smaller samples most of those who committed suicide were psychiatrically ill prior to their spouses' deaths. A case control study of 100 elderly suicides compared

to well-matched deaths from other causes, found that the major independent risk factors in those who committed suicide were family discord and mental disorders (mainly depression and substance abuse). Recent bereavement did not distinguish the two groups.

Pathologic Outcomes and Predictors of Outcome

Before reviewing the predictors of pathologic outcomes it should be noted that all studies of widowhood, including those on mortality, emphasize that psychological stability predicts a good outcome, although unfortunately no-one has measured personality traits or variables prior to entry into widowhood. Good health predicts a better outcome. And not having sleep difficulty or having low scores on depression ratings in the first month of bereavement also predicts a better outcome.

There are many ways to assess outcome. Loneliness certainly is the most characteristic outcome following bereavement and this persists in many for years. Under psychological morbidity, chronic depression as measured 1 year after the death and complicated bereavement both lead to a significant morbidity. There is also physical morbidity. The mortality noted postbereavement still needs further study.

There are very few definitive predictors of chronic depression. A past history of psychiatric illness particularly depression predicts it, poor prior physical health may predict it, and depression at 1 month after the bereavement definitely predicts it. Perhaps a bereavement that follows an instantaneous and totally unexpected death predicts it, although it might not be that it is the unexpected aspect of it, but rather whether it is violent in nature. Studies will clarify the predictions as data collection improves. All the other variables, gender, young age, perceived lack of social supports and socioeconomic income do not predict it. Gender is important to note, because major depression is overwhelmingly more common in women than in men but chronic depression after bereavement is not. Stress-related depression affects both genders equally.

Treatment

The vast majority of people who experience a loss will recover gradually without any interventions. It is just that fact that probably contributes to the conclusion in a recent salient review of all qualifying grief counseling studies, which the effect of such counseling is quite weak and in some cases could even be harmful.

In those who become chronically depressed or have complicated grief, an intervention at 6 months after

the bereavement is indicated. In a recent report, 95 volunteers with complicated grief of long duration (>2 years) were randomized to treatment with either interpersonal therapy (IPT) or complicated grief therapy (IPT modified to include cognitive therapy based on techniques for addressing trauma). The results showed, when looking at treatment completers, the complicated grief therapy was superior to IPT especially in those with losses through violent deaths. Still, the response rate was only 51%. Patients also had high rates of comorbid depression and PTSD and 45% were taking antidepressants. It may be the kind of therapy for a specific group of bereaved that Jordan and Neimeyer (2003: 765) were urging researchers to study. Most importantly, the elements of these therapies may be applicable to other stress-related disorders.

Antidepressants have also been used and been shown to be efficacious. For example, an older study of treatment of bereavement-related major depressive episodes in later life with nortriptyline, IPT, the combination, or neither showed that nortriptyline alone or with IPT significantly improved the depressive disorder. IPT alone was not significantly different to the placebo. The outcomes are notable because very few people relapsed when the treatments were stopped and the response rate was relatively high in both nortriptyline treatment groups and the placebo group. Thus it seems to be a good condition to treat with antidepressant medication. It is also important to remember that should the patient be psychotic or suicidal, electroconvulsive therapy (ECT) is probably indicated.

Summary

Glossary

Adrenergic receptors

Specific molecular recognition sites for norepinephrine or epinephrine located on cell membranes in the central or peripheral sympathetic nervous system. These receptors are coupled with G-proteins (proteins that bind guanosine triphosphate and hydrolyze it to guanosine monophosphate) that act as transducers for intracellular second messenger systems such as cyclic adenosine monophosphate. In turn, these second messenger systems may mediate a number of biological responses, ranging from ion channel effects to release of neurotransmitters to regulation of gene expression.

Anxiety

Apprehension of danger and dread accompanied by restlessness, tension,

<i>Autoreceptors</i>	tachycardia, and dyspnea unattached to a clearly identifiable stimulus. Sites on the nerve axon terminal that respond to the neuron's own neurotransmitter.
<i>β-Adrenergic antagonist</i>	A drug that prevents stimulation of the β-adrenergic receptors of the nerves of the sympathetic nervous system and therefore decreases the activity of the heart and reduces the blood pressure, and may have other properties such as reduction of physiological symptoms of anxiety.
<i>Norepinephrine</i>	A hormone, closely related to epinephrine and with similar actions, secreted by the medulla of the adrenal and also released as a neurotransmitter by sympathetic nerve endings and by axonal projections from the neurons in the locus ceruleus in the brain.
<i>Posttraumatic stress disorder</i>	An anxiety disorder developing in persons who have experienced a physically or emotionally traumatic event that is outside of the range of normal human experience, such as combat, physical assault, rape, or disasters such as home fires.
<i>Stress</i>	Any factor that threatens the health of the body or has an adverse effect on its functioning, such as injury, disease, or worry.

Introduction and Definition

The β-adrenergic receptor antagonists have been used since the late 1950s for the treatment of hypertension, cardiac arrhythmias, angina, thyrotoxicosis, glaucoma, migraine, tremor, and, in psychiatry, anxiety, akathisia, and other syndromes. Development of propranolol, the prototype β-blocker, followed Ahlquist's hypothesis that the effects of catecholamines are mediated by α- and β-adrenergic receptors.

β receptors are widely distributed in the vasculature and in neurons of the central and peripheral nervous system. The β receptors are stimulated by norepinephrine. Noradrenergic systems are likely critical in mediating anxiety and stress response. Thus, there has long been interest in β-blockers in psychiatry because of their pharmacological effects in dampening behavioral or physiological responses to noradrenergic stimulation. Agents that have been most frequently studied in various psychiatric disorders include propranolol (Inderal), metoprolol (Lopressor), nadolol (Corgard), acebutolol (Sectral), labetalol (Normodyne Trandate), pindolol (Visken), and atenolol (Tenormin).

Chemistry

The β-blockers share structural similarity with dichloroisoproterenol, first synthesized in the 1950s. However, dichloroisoproterenol is a partial agonist, an action that was thought to preclude its use clinically. The first pure antagonist, pronetholol, was associated with thymic tumors in mice. Propranolol, the next compound to be developed, became the prototype β-blocker. The chemical designation, molecular formula and molecular weight of seven representative β-blockers are shown in [Table 1](#). The molecular structures are illustrated in [Figure 1](#).

Pharmacology

Pharmacodynamics

The β-blockers are competitive antagonists of norepinephrine and epinephrine β-adrenergic receptors. Epinephrine and norepinephrine are released as stress hormones from the adrenal medulla. Norepinephrine is also released from neurons in the peripheral sympathetic nervous system. These catecholamines are

Table 1 Basic chemistry of selected β-blockers

<i>β-Blocker</i>	<i>Chemical designation</i>	<i>Molecular formula</i>	<i>Molecular weight</i>
Acebutolol	± N-[13-acetyl-4-[2-hydroxy-3-1[(methylethyl)amino] propoxy]phenyl]butanamide	C ₁₈ H ₂₈ N ₂ O ₄ HCL	327.90
Atenolol	4-[2'-hydroxy-3'-[(1-methylethyl)amino]propoxy]-phenyl]ethanamide	C ₁₄ H ₂₂ N ₂ O ₃	266.00
Labetalol	5-[1-hydroxy-2-[(1-methyl-3-phenylpropyl)amino]ethyl]salicylamide conochloride	C ₁₉ H ₂₄ N ₂ O ₃	364.9
Metoprolol	1-(isopropylamino)-3-[p-(2-methoxy-ethyl)phenoxy]-2-propanol(2:1) dextro-tartrate salt	C ₃₄ H ₅₆ N ₂ O ₁₂	684.82

Propranolol	1-(isopropylamino)-3-(1-naphthyl)-2-propanol hydrochloride	OCH ₂ CHOHCH ₂ NHCH(CH ₃) ₂	295.81

Figure 1 Molecular structures of the β -adrenergic receptor antagonists.

involved in cardiovascular regulation and stress responses. In the central nervous system (CNS), norepinephrine is produced by neurons in the brain stem tegmentum. The locus ceruleus is the primary noradrenergic nucleus, with widespread projections to the spinal cord, cortex, limbic regions, and cerebellum. CNS noradrenergic systems are involved in emotional regulation, learning and memory, pain perception, control of blood pressure, and the neuroendocrine response to stressful stimuli.

The effects of norepinephrine in the brain are mediated by two classes of receptors: α and β receptors. These are further divided into α_1 and α_2 and β_1 and β_2 and β_3 subtypes. Activation of α_1 receptors produces neuronal excitation partly linked to phosphoinositide activation. α_2 receptors are inhibitory autoreceptors that decrease norepinephrine release. Consequently, α_2 receptor activation reduces both central and peripheral noradrenergic activity. α_2

receptors are located in the CNS on locus ceruleus noradrenergic neurons. Clonidine is an example of an α_2 agonist with antihypertensive properties due to reduction in noradrenergic activity. In contrast, yohimbine, an α_2 receptor antagonist, may release norepinephrine, resulting in anxiety due to central noradrenergic activation and vasoconstriction in the periphery.

β receptors are widely distributed in both the CNS and the periphery. β_1 receptors are localized in the cardiac sinoatrial and atrioventricular nodes and myocardium. β_2 receptors are located in the pulmonary bronchi, the eye, peripheral vasculature, bladder and uterus, and liver (where they mediate glucose metabolism). β_2 and β_3 receptors are also involved in lipid metabolism.

The numerous β -blockers vary based on their relative pharmacokinetics, pharmacodynamics, and lipid solubility. Examples of these differences include

relative β_1 versus β_2 antagonism, intrinsic sympathomimetic properties, α -adrenergic receptor affinity, lipid solubility, direct vasodilator properties, certain pharmacokinetic properties, and effects on other neurotransmitter systems (e.g., serotonergic properties). Lipid solubility is important because entry of drug into the brain is dependent on its ability to cross the blood–brain barrier, which is a highly lipid structure. The lipid solubility properties of the seven representative β -blockers are shown in [Table 2](#).

Propranolol is a nonselective β_1 and β_2 antagonist. Atenolol is a relatively selective β_1 antagonist. [Table 2](#) shows the relative β_1 versus β_2 affinities for the commonly used β -blockers.

Pharmacokinetics

Propranolol is almost completely absorbed following oral administration. Nadolol, atenolol, and metoprolol are partially absorbed. Nadolol, in contrast to the other listed agents, has a relatively long plasma half-life that allows once-daily dosing. Propranolol is avidly protein bound (90%) and undergoes extensive hepatic metabolism. In contrast, nadolol and atenolol are not as extensively metabolized and undergo renal excretion.

Nadolol and atenolol are the least lipophilic of the β -blockers and therefore have less penetrance of the blood–brain barrier, yielding more peripheral as opposed to central effects. In contrast, propranolol and metoprolol are more lipophilic and therefore have relatively greater CNS effects. Pindolol is of intermediate lipophilicity – this agent has been of recent interest as a possible antidepressant-potentiating drug due to its intrinsic sympathomimetic activity and serotonergic effects. All of the β -blockers are excreted in human milk and therefore should be used with caution in nursing mothers.

Role in Stress, Learning, and Memory

An extensive preclinical and clinical literature suggests that the CNS noradrenergic system is an important mediator in human as well as in animal response to stress. As such, β -blockers are of interest because of their ability to dampen noradrenergic hyperarousal. There is also emerging evidence from both preclinical and human studies to suggest that β -blockers may attenuate learned responses or memory subsequent to anxiety-provoking stimuli. These latter data suggests that β -adrenergic activation may be required for certain memories associated with emotional arousal.

Animal studies suggest that the β -adrenergic system is involved in enhancing memory associated with

stress. In humans, administration of propranolol selectively impaired memory for an emotionally laden story but did not impair memory for a matched but emotionally neutral story. This latter observation suggests that emotional memory in humans may be affected by β -blockers. Of great interest in recent studies is the utility of these agents in attenuating memories associated with acute stress in emotionally traumatized individuals and whether the long-term sequelae (e.g., posttraumatic stress disorder [PTSD]) could therefore be minimized. Another question for study is whether patients taking β -blockers chronically might have subtle impairment in memory for emotionally significant events.

Therapeutic Use in Psychiatry

Anxiety Disorders

An extensive literature suggests that β -blockers may reduce autonomic symptoms in patients with panic disorder, generalized anxiety disorder, social phobia, and PTSD. They may not be as useful for subjective or cognitive anxiety (e.g., fear, worry, dread, or intrusive memories).

Social phobia Social phobia may include anxiety in specific social situations (e.g., giving a speech [performance anxiety]) or be generalized to a number of different social situations (generalized social phobia). Social phobia can result in significant occupational as well as social difficulties. β -blockers are helpful in specific performance anxiety when used on an as-needed basis but do not appear helpful for generalized social phobia. In performance anxiety, the β -blockers reduce autonomic symptoms associated with the performance situation (e.g., tremor, tachycardia, and diaphoresis). A test dose of the β -blocker should be administered at home before the individual gives the actual performance to ensure tolerability. Customary dose ranges of β -blockers used in social phobia may be 10 to 40 mg daily for propranolol or 50 to 100 mg daily for atenolol. For specific or discrete performance anxiety, the dose should be given 1 to 2 h before the activity.

Two studies have been consistent with the common clinical impression that β -blockers are not effective in generalized social phobia. A trial of atenolol versus placebo or phenelzine in social phobia showed better efficacy for phenelzine as compared with placebo or atenolol. Atenolol was comparable to placebo. Similarly, a placebo-controlled trial of behavior therapy versus atenolol or placebo in the social phobia was consistent with superior efficacy for behavior therapy, with atenolol being comparable to placebo.

Table 2 Comparative pharmacological properties of selected β -blockers

	<i>Relative β receptor selectivity</i>	<i>α_1 antagonist properties</i>	<i>Sympathomimetic properties</i>	<i>Direct vasodilator activity</i>	<i>Metabolism</i>	<i>Excretion</i>	<i>Plasma half-life (h)</i>	<i>Protein binding (%)</i>	<i>Lipid solubility</i>

Atenolol	$\beta_1 > \beta_2$	—	+	—	Minimal	Renal 50%, nonrenal 50%	6–7	6–16	Low
Labetolol	$\beta_1 = \beta_2$	+++	—	—	Hepatic	Renal 30–40%, nonrenal 50–60%	6–8	50	Moderate
Metoprolol	$\beta_1 > \beta_2$	—	—	—	Hepatic	Renal $\leq 5\%$, nonrenal $\geq 95\%$	3–7	12	High
Nadolol	$\beta_1 = \beta_2$	—	—	—	Minimal	Renal 65–70%, nonrenal 30–35%	14–24	30	Low
Pindolol	$\beta_1 > \beta_2$	—	—	—	Hepatic	Renal 35–40%, nonrenal 60–65%	3–4	40	Moderate
Propanolol	$\beta_1 = \beta_2$	—	—	—	Hepatic	Renal 90–95%, nonrenal 5–10%	4	90	High

Posttraumatic stress disorder PTSD is a chronic anxiety disorder that may occur after a severe life-threatening stress (e.g., combat or rape). Symptoms include reexperiencing the trauma via intrusive memories, flashbacks (sudden acting or feeling as if the trauma was recurring), nightmares, avoidance of reminders of the trauma, and symptoms of increased autonomic arousal (e.g., exaggerated startle, hypervigilance, and insomnia). PTSD can result in severe occupational and social impairment. A number of clinical studies have suggested norepinephrine hyperactivity in PTSD. For example, exaggerated norepinephrine or norepinephrine metabolite responses may occur secondary to pharmacological, psychological, or physical stressors.

Despite the evidence for noradrenergic hyperarousal in PTSD, there has been surprisingly little study to date of β -blockers in the disorder. Two of three clinical reports were promising in suggesting potential efficacy. One report suggested that propranolol may reduce intrusion and arousal symptoms in Vietnam veterans with PTSD. In contrast, propranolol was not efficacious in an open trial in Cambodian refugees with PTSD. Another report in children with PTSD who were victims of physical or sexual abuse suggested that propranolol at a dose of 2.5 mg/kg/day could reduce both reexperiencing and hyperarousal symptoms. Controlled studies are needed in both chronic as well as acutely traumatized populations. The potential role of β -blockers in modifying memory related to acute emotional trauma, as discussed in the previous section, is especially intriguing. Of note, several pilot studies have suggested that propranolol may mitigate or perhaps prevent the development of PTSD if administered shortly following acute trauma exposure. More study is needed of these encouraging preliminary reports before this could be considered a standard clinical practice.

Panic disorder and generalized anxiety disorder The β -blockers can reduce autonomic symptoms associated with generalized anxiety disorder (GAD) or panic attacks but do not appear effective for cognitive or psychological aspects of anxiety (e.g., worry, fear, or dread). This is likely because β_1 but not β_2 receptors are located in the brain and β_2 blockade does not appear to affect psychological anxiety. The psychological and cognitive symptoms respond better to benzodiazepines, buspirone, or antidepressants. There are also negative reports on the efficacy of β -blockers in panic and anxiety.

Doses of propranolol used in GAD range from 40 to 320 mg/day in two to four divided doses. A preliminary clinical report suggested that a long-acting

β -blocker, betaxolol, in doses of 5 to 20 mg daily were effective in GAD patients. Betaxolol, a relatively β_1 -selective agent, penetrates the CNS to a much greater extent than other long half-life agents such as nadolol or atenolol. Recent reports have suggested that pindolol may augment the therapeutic response to antidepressants in treatment-refractory panic disorder. For example, a placebo-controlled trial in panic disorder patients refractory to two antidepressant trials and to a trial of fluoxetine responded to the addition of pindolol given at a dose of 2.5 mg three times daily.

Obsessive-compulsive disorder Pindolol may augment the therapeutic effect of antidepressants in patients with treatment-resistant obsessive-compulsive disorder (OCD). For example, a double-blind, placebo-controlled trial of adding pindolol to the selective serotonin reuptake inhibitor paroxetine showed significant improvement in OCD ratings for patients receiving pindolol 2.5 mg orally three times daily (see also antidepressant potentiation section below).

Aggression and Violence

A number of case reports, clinical series, and controlled studies suggest that β -blockers can reduce aggression associated with chronic psychotic disorders, dementia, and head trauma. Behaviors such as impulsivity, largely attributable to orbitofrontal cortical dysfunction, are most likely to respond to β -blockers. This may reflect the extensive frontocortical noradrenergic afferent projections. Relatively lipophilic agents (e.g., propranolol, metoprolol, or nadolol) have been utilized because of their CNS effects. Doses of propranolol or equivalent β -blocker used in treating violent behaviors range from 40 to 520 mg/day in divided doses. Many of the clinical reports involve violent patients refractory to other medications (e.g., antipsychotics or mood stabilizers). For example, nadolol at a dose of 120 mg/day may be more effective than placebo as an adjunct to antipsychotics in aggressive schizophrenic patients. Elderly patients with dementia and associated aggression or agitation may improve with lower doses of propranolol (10–80 mg/day) than are used in younger aggressive patients. An important confound in interpreting the controlled trials of β -blockers in violence is the episodic nature of aggressive behavior. Also, most studies of β -blockers in violence have involved drug combination rather than monotherapy. For patients who have not responded to other psychotropics, a β -blocker trial may be indicated with close monitoring for adverse effects (e.g., hypotension),

especially in light of the high doses needed for therapeutic effect.

Alcohol Withdrawal

Alcohol withdrawal in part involves autonomic instability mediated by significant CNS and peripheral noradrenergic activation. The β -blockers therefore can help reduce certain autonomic symptoms. Unlike the benzodiazepines, β -blockers are not cross-reactive with alcohol, so they are not likely to be effective as a monotherapy for alcohol detoxification. They may be effective as an adjunctive agent to benzodiazepines or other first-line withdrawal agents. A randomized, double-blind trial of atenolol as an adjunct to benzodiazepines found that administration of atenolol based on heart rate parameters improved vital signs and tremor more rapidly than placebo and resulted in less benzodiazepine use and decreased length of hospitalization. Atenolol was administered based on the following heart rate parameters: less than 50 beats/min, no drug; 50 to 79, 50 mg once daily; greater than 80, 100 mg daily. Further study is needed of this potential adjunctive use of β -blockers.

Treatment of Medication Side Effects

Antipsychotic-induced akathisia Akathisia is motor restlessness associated with antipsychotics, in particular the first-generation or traditional agents such as chlorpromazine (Thorazine), fluphenazine (Prolixin), or haloperidol (Haldol). Categorized as an extrapyramidal system side effect (EPS), akathisia can result in substantial noncompliance with antipsychotic medication. Unlike other EPSs such as parkinsonism, akathisia may respond better to β -blockers or benzodiazepines than antiparkinsonism medication such as benztropine (Cogentin). The EPSs in general are thought secondary to blockade of dopamine (D_2) receptors in the nigrostriatal pathway. The D_2 receptor blockade is common to all antipsychotic agents, although the new generation or atypical antipsychotics may have reduced akathisia incidence, perhaps due to their higher ratio of serotonin-to-dopamine receptor blockade. Akathisia differs somewhat from other EPSs in that the mechanism may involve loss of tonic dopamine inhibition of the locus ceruleus due to D_2 receptor blockade. The resulting increased noradrenergic release from the locus ceruleus results in the subjective anxiety and motor restlessness characteristic of akathisia. This mechanism may explain the enhanced efficacy of β -blockers or benzodiazepines, both of which decrease noradrenergic function (β -blockers via postsynaptic receptor blockade and benzodiazepines via decreased locus ceruleus firing rate)

as opposed to antiparkinson agents such as Cogentin or Symmetrel.

For treatment of akathisia, propranolol is given in doses of 10 to 30 mg three times daily (or similar doses of other β -blockers may be considered). β -blockers may be given alone or in combination with benzodiazepines or antiparkinsonism medications. The new generation or atypical antipsychotics have less potential to induce akathisia.

Lithium-induced tremor The low-amplitude action tremor characteristic of lithium may occur at therapeutic or even subtherapeutic doses. In fact, new-onset or worsening of the tremor (higher amplitude, increased frequency) may be a warning sign for lithium toxicity. A stable tremor at therapeutic doses can cause motor dysfunction (e.g., difficulty writing) and therefore may require treatment to enhance lithium tolerability as well as compliance. Lithium should be given at the lowest effective maintenance dose.

Analogous to their use in benign essential or familial tremor, β -blockers (e.g., propranolol in the daily dose range of 20 to 100 mg, in two or three divided doses) can be effective. In addition to the patient being maintained on the lowest effective lithium dose, administration of a single nighttime dose of lithium (which may also reduce lithium-associated renal morphological changes) and reduction of caffeine consumption can help minimize the tremor.

Antidepressant Potentiation

Several reports have suggested that the β -blocker pindolol, which increases forebrain neuronal release of serotonin in animals, may potentiate and possibly reduce the latency of response to selective serotonin reuptake inhibitor antidepressants. Pindolol is a lipophilic and relatively nonselective β_1 - and β_2 -blocker that also has intrinsic sympathomimetic properties. The serotonin augmentation is likely due to its selective serotonin 5-HT_{1A} receptor effects. Whether β -blockers may cause or exacerbate depression remains controversial.

Therapeutic Use in Medical Disorders

The β -blockers, originally developed for the treatment of hypertension and angina, had expanded roles in clinical medicine as antiarrhythmics, prevention of cardiovascular mortality after myocardial infarction, treatment of complications of cardiomyopathies, and various other noncardiovascular as well as psychiatric uses (Table 3).

Table 3 Doses of β -blockers used in psychiatry

<i>Generic name</i>	<i>Trade name</i>	<i>Usual starting dose (mg)</i>	<i>Usual maximum dosage (mg)</i>
Acebutolol	Sectral	400 qd	600 bid
Atenolol	Tenormin	50 bid	75–150 bid
Labetalol	Normodyne, Trandate	100 bid	400–800 bid
Metoprolol	Lopressor	50 bid	75–150 bid
Nadolol	Corgard	40 qd	80–240 qd
Pindolol	Visken	5 bid	30 bid
Propranolol	Inderal	10–20 bid or tid	80–140 bid or tid

Hypertension

The β -blockers are effective as a monotherapy or in combination with other antihypertensives. They may reduce morbidity (e.g., left ventricular hypertrophy) and mortality associated with hypertension.

Angina Pectoris

The β -blockers are useful in monotherapy or in combination with certain antianginals including nitrates and some calcium channel blockers. The reduction in symptoms, especially in exertional angina, is attributable to decreased cardiac workload due to slower heart rate allowing longer diastolic filling time and improved coronary artery perfusion.

Cardiac Arrhythmias

The β -blockers are efficacious in controlling supraventricular tachyarrhythmias and reduction of ventricular arrhythmias. The mechanism includes decreased heart rate by reduced adrenergic stimulation of sinoatrial or atrioventricular node pacemakers and by cardiac membrane stabilization.

Congestive Heart Failure

The β -blockers may reduce symptoms and improve functional status in congestive heart failure (CHF) patients with careful administration. They may be indicated for patients who continue to be symptomatic with standard therapies. However, β -blockers may also precipitate CHF. Their use in dilated cardiomyopathy is based on the theory that they may attenuate the adverse effects on cardiac function of excessive adrenergic stimulation secondary to CHF.

Other Medical Uses

Additional medical diseases in which the reduction of excessive adrenergic stimulation with β -blockers may be useful include acute dissecting aortic aneurysm, dilation of the aorta associated with Marfan's syndrome (propranolol), pheochromocytoma, glaucoma, hyperthyroidism, tremors, migraine prophylaxis, and portal hypertension. Different β -blockers are used

in these various indications depending on their relative pharmacological effects (e.g., relative β_1 versus β_2 antagonism or degree of vasodilating properties).

Safety and Tolerability

Side Effects

The β -blockers are generally well-tolerated. Side effects are listed in [Table 4](#). The more frequent side effects are a consequence of the pharmacodynamic effects (i.e., β_1 and, if applicable, β_2 receptor blockade). These more common side effects include hypotension, dizziness, bradycardia, and sexual dysfunction. The β_1 -selective agents have decreased risk of bronchospasm (asthma exacerbation) than those with β_2 effects. Cardiovascular side effects can be minimized by careful dose titration, monitoring pulse and blood pressure, and patient education. Patients with coronary heart disease can have exacerbation of angina pectoris with discontinuation (especially abrupt withdrawal) of β -blockers. There may also be rebound hypertension in patients with a history of hypertension and worsening of CHF. Diabetic patients may have increased glucose dysregulation (especially hypoglycemia) and may have decreased autonomic symptoms of hypoglycemia (i.e., less subjective awareness of warning symptoms) due to β -blockade. The β_1 agents overall are safer to use in patients with bronchospasms, peripheral vascular disease, Raynaud's disease, and diabetes. Importantly, topically administered β -blockers (e.g., for glaucoma patients) can have systemic effects. Insomnia and nightmares are associated with sleep architecture changes from most β -blockers, although some (e.g., betaxolol) may have fewer adverse sleep effects. Although fatigue or lassitude may occur in some individuals with chronic β -blocker administration, clinical depression is probably rare as a causal association. CNS effects may be minimized by using peripheral-acting (less lipophilic) agents.

Use in Pregnancy

The β -blockers should be used with caution in pregnant or nursing women and only if the benefit clearly

Table 4 Side effects of β -blockers

Cardiovascular
Hypotension
Bradycardia
Lightheadedness or dizziness
Congestive heart failure (with predisposing cardiac disease)
Atrioventricular block

Psychosis (rare)

outweighs potential risks. All of the β -blockers are pregnancy category C, which means there are insufficient data in humans to demonstrate safety in pregnancy or to show definite relationship with defects. Embryotoxicity and neonatal toxicity have been observed in animals given β -blockers. There are no adequate studies in pregnant women. There are reports of intrauterine growth retardation and neonatal toxicity (bradycardia, hypoglycemia, and respiratory depression) in neonates of mothers treated with β -blockers. The safety and efficacy of β -blockers in children is not well established.

Drug Interactions

Of primary concern are pharmacodynamic interactions with other antihypertensive agents (e.g., clonidine or reserpine [postural hypotension]), atrioventricular block with other antiarrhythmics (e.g., digoxin or verapamil), or agents that have negative cardiac inotropic effects (e.g., diltiazem). There are several pharmacokinetic interactions: alcohol, cholestyramine, and aluminum hydroxide gels reduce absorption of β -blockers. Phenytoin, rifampin, and phenobarbital and smoking increase hepatic clearance of extensively metabolized β -blockers. Antipyrine, lidocaine, and theophylline have reduced clearance by β -blockers.

Cimetidine decreases hepatic metabolism of propranolol and metoprolol.

Summary

β -blockers have been among the most useful and effective class of compounds used for medical, neurological, and psychiatric conditions. Since their introduction to clinical medicine in the late 1960s, they have been effective in the treatment of cardiovascular, endocrine, neurological, and various psychiatric illnesses, especially anxiety disorders, drug-induced toxicities (e.g., akathisia and tremor), and, recently, potentiation of antidepressant effect in some treatment-resistant disorders.

The possible use of β -blockers to attenuate or reduce the impact of situational trauma or PTSD needs further exploration. Doctors are learning about the importance of the use of selective serotonin reuptake inhibitors to possibly improve the course of affective illness or advance episode frequency. In an analogous fashion, the potential role of β -blockers for prevention and prophylaxis of stress-related disorders needs further study.

Glossary

<i>Adrenocorticotropin (ACTH)</i>	The pituitary hormone that regulates adrenal corticosteroid synthesis and release. ACTH, like β-endorphin, is derived from proopiomelanocortin.
<i>Endogenous opioid peptides</i>	Peptides with morphine-like actions that are synthesized in the brain and in peripheral tissues.
<i>Endorphins</i>	A general term that refers to all of the endogenous opioid peptides. β-endorphin refers to a specific peptide.
<i>Naloxone</i>	A compound that binds to opiate receptors and blocks the effects of morphine and the endogenous opioid peptides.
<i>Proopiomelanocortin</i>	The larger precursor protein from which β-endorphin is derived.

β -endorphin is an endogenous opioid peptide that is synthesized primarily in the pituitary gland and in the brain. Stress stimulates the release of β -endorphin in both the pituitary and the brain. β -endorphin and the other endogenous opioid peptides have been implicated in analgesia and in neuroendocrine regulation during times of stress, including the suppression of reproductive function. These peptides also play a role in autonomic regulation, modulation of cardiovascular responses and cerebral blood flow, and the regulation of behavior and immune function.

Structure, Synthesis, and Localization

β -Endorphin is a 31-amino-acid peptide that is derived from the larger molecular weight precursor protein proopiomelanocortin (POMC). β -Endorphin is one of the three major classes of endogenous opioid peptides. The other two classes are composed of the enkephalins and the dynorphins, which are derived from separate precursor proteins. POMC is synthesized independently in the anterior and intermediate lobes of the pituitary gland, in the brain, and in several peripheral tissues, including the gastrointestinal tract, reproductive tract, placenta, and cells of the immune system. The posttranslational processing of POMC is tissue specific and results in the production of peptides with very different biological activities. In the anterior pituitary, POMC is processed predominantly to adrenocorticotropin (ACTH) and β -lipotropin (β -LPH), but some β -endorphin is also produced. ACTH is secreted from the pituitary into the peripheral circulation and is critical for the maintenance of adrenocortical function and cortisol secretion. β -endorphin is also secreted in parallel with ACTH. In the brain, ACTH and β -LPH are further processed to yield α -melanocyte-stimulating hormone (α -MSH) and β -endorphin. The regulation of POMC processing is potentially important, as α -MSH has been shown to antagonize some of the effects of β -endorphin. The regulation of POMC gene expression and peptide release is also tissue specific, but under conditions of stress, β -endorphin is released from both the pituitary and the brain. The hypothalamic releasing factor corticotropin-releasing hormone (CRH), which plays a key role in coordinating the organism's response to stress, has been shown to stimulate pituitary and brain β -endorphin. β -endorphin exerts its effects by binding to specific opioid receptors, particularly the mu and delta receptors, which have been recently cloned and localized throughout the brain.

β -Endorphin is released from the anterior pituitary into the peripheral circulation in parallel with ACTH

in response to a variety of stresses. Numerous studies have documented parallel increases in peripheral blood levels of ACTH and β -endorphin in response to exercise. This appears to be related to the intensity and duration of the exercise. A number of correlations between β -endorphin levels in blood and central nervous system or cardiovascular responses during stress have been reported. One must be cautious, however, in attributing a causal relationship for circulating β -endorphin, because in many instances, brain β -endorphin may also be stimulated at the same time. In addition, peripherally released β -endorphin does not readily cross the blood-brain barrier. In the brain, β -endorphin is synthesized in only two regions, the arcuate nucleus of the hypothalamus and the nucleus of the solitary tract in the brain stem, but β -endorphin fibers project widely to many regions throughout the brain.

β -Endorphin and Neuroendocrine Responses

Endogenous opioid peptides have multiple effects on pituitary function. Effects on gonadotropin (luteinizing hormone [LH] and follicle-stimulating hormone [FSH]), prolactin, ACTH, vasopressin, and oxytocin release have all been demonstrated. There is evidence for a specific role for β -endorphin during stress with respect to the regulation of LH and the hypothalamic-pituitary-gonadal (HPG) axis, of ACTH and the hypothalamic-pituitary-adrenocortical (HPA) axis, and of prolactin release. Stress is known to impair reproductive function in many species. Stress has been shown to suppress the release of LH from the pituitary with subsequent suppression of ovarian and testicular function. Such suppression has been seen with many types of stress ranging from exercise and weight loss to inflammatory and psychological stress. CRH, which is released from the hypothalamus during stress, has been shown to cause a similar suppression of the HPG axis. There is convincing evidence that the suppressive effects of stress and CRH on the HPG axis are mediated by β -endorphin. Thus, both CRH and β -endorphin are important in suppressing reproductive function during times of stress. Exogenous and endogenous opioids also have well-documented effects on the HPA axis. There are some differences, however, depending on the dose and duration of treatment and the species studied. In the human, morphine and β -endorphin have been shown to suppress ACTH and cortisol release in normal subjects and to blunt the HPA response to surgical stress. β -Endorphin has been shown to suppress CRH release from the hypothalamus *in vitro*

and to suppress CRH release into hypophysial portal blood *in vivo*. Conversely, opioid antagonism has been reported to stimulate the HPA axis and to enhance the HPA response to stress. Thus, β -endorphin may be important in limiting the HPA response under conditions of stress.

β -Endorphin and Stress-Induced Analgesia

It has long been known that pain perception is affected by stress. Electrical stimulation of specific brain regions has been shown to induce analgesia that was blocked by treatment with naloxone and other opioid antagonists, implying that this analgesia was mediated by the release of endogenous opioids. Certain forms of stress-induced analgesia are also blocked by naloxone. It is now clear that stress-induced analgesia is mediated by both opioid and nonopioid pathways. There is considerable pharmacological and neuroanatomic evidence to implicate β -endorphin as a mediator of stress-induced analgesia. Recently, a genetic approach has been used to generate mice that are unable to synthesize β -endorphin. These transgenic mice do not exhibit the naloxone-reversible analgesia normally seen after a mild swim stress, supporting a role for β -endorphin in this process. β -Endorphin is also synthesized by immune cells and is known to play a role in mediating analgesia at sites of inflammation. Studies in rats have demonstrated that β -endorphin is released by immune cells at sites of inflammation and can induce analgesia by interaction with receptors on peripheral terminals of sensory nerves. These studies provide convincing evidence that β -endorphin plays an important role within the brain in mediating stress-induced analgesia and can also act locally to affect pain perception at sites of inflammation.

β -Endorphin and the Immune System

Both stress and opioids have suppressive effects on immune function. Naloxone has also been shown to block stress-induced immune suppression, indicating a role for endogenous opioids in this process. β -Endorphin-deficient mice possess enhanced immune responses as measured by increased splenocyte proliferation and inflammatory cytokine production, consistent with an inhibitory effect of endogenous β -endorphin on immune function. β -Endorphin is produced by cells of the immune system and may have local paracrine effects on immune function. Circulating, pituitary-derived β -endorphin, which increases with stress and with inflammation, may also affect immune function. In addition, β -endorphin may affect

immune function indirectly by modulating neuroendocrine and autonomic function.

β -Endorphin and Cardiovascular Responses

The endogenous opioid peptides are localized to regions within the brain that are important in controlling the autonomic nervous system and cardiovascular responses. β -Endorphin is synthesized in the nucleus of the solitary tract in the medulla, an area important in cardiovascular regulation. The effects of opioids on cardiovascular function are complex and depend on the type of opioid injected, the site of injection, and whether the animal is anesthetized or stressed. Although discrepancies exist, it appears that in general, opioids diminish stress-induced cardiovascular effects. Opioid mechanisms appear to facilitate parasympathetic and inhibit sympathetic nervous system reactivity during stress. High-dose infusion of β -endorphin in human subjects reduces blood pressure and circulating norepinephrine levels. Several studies have demonstrated activation of the endogenous opioid system in hemorrhagic shock, sepsis, and trauma and shown that this system plays a complex role both centrally and peripherally in modulating autonomic and cardiovascular responses. Endogenous opioid peptides are also important in regulating cerebral blood flow, especially during periods of hypoxia. β -Endorphin, in particular, has been shown to regulate hypothalamic blood flow.

β -Endorphin and Stress-Induced Feeding and Other Behaviors

Pharmacological studies have shown that opioids generally stimulate food intake. Rats subjected to mild stress exhibit stress-induced eating that can be attenuated by treatment with naloxone, thus implicating a role of endogenous opioids in this process. β -Endorphin administration in rodents has also been shown to stimulate food intake. However, more recently, studies with transgenic mice deficient in β -endorphin indicate that the role of endogenous opioids in modulating feeding and energy homeostasis is quite complex and that β -endorphin may be important in primarily increasing the motivational and reward components of feeding. Finally, there is evidence that endogenous opioids may affect other behavioral and psychological responses to stress, but a specific role for β -endorphin remains to be defined.

Blood Pressure Measurement

Hypertension

Stress and Blood Pressure

Ambulatory Blood Pressure

Glossary

Ambulatory blood pressure Measurements recorded during the course of normal daily activities, using a wearable blood pressure monitor.

Cardiac output

The volume flow rate (l/min) of blood ejected from the left ventricle of the heart into the systemic circulation.

Diastolic blood pressure

The lowest pressure (mmHg) in the arterial system, occurring during cardiac diastole.

Hemo-dynamics

Assessment of the circulation in terms of blood pressure, cardiac output, and systemic vascular resistance.

Hypertension

Resting blood pressure that is higher than 140/90 mmHg.

Reactivity

A psychophysiological trait expressed as cardiovascular response to one or more psychological stressors.

Sympathetic nervous system

A division of the autonomic nervous system that is activated in association with psychological stress and is involved in cardiovascular regulation.

Systemic vascular resistance

The total peripheral resistance of the systemic vasculature (dynes s cm⁻⁵).

Systolic blood pressure The highest pressure (mmHg) in the arterial system, occurring during cardiac systole.

Blood Pressure Measurement

When the left ventricle of the heart contracts, a bolus of blood is ejected into the systemic circulation, creating a pulse pressure waveform that propagates through the arterial tree. The peak pressure reached in the arterial system is referred to as systolic pressure, since it occurs in association with cardiac systole, or the heart's contraction phase. Once systolic pressure is reached, pulsatile pressure falls as the heart relaxes during diastole, with the lowest pressure, referred to as diastolic pressure, occurring just prior to the onset of the next systolic phase. Pulse pressure is defined as the difference between systolic and diastolic pressure. Mean arterial pressure refers to the average pressure in the arterial system. All blood pressure measurements are recorded in millimeters of mercury (mmHg).

Systolic and diastolic pressure are the most commonly measured aspects of arterial blood pressure. The emphasis on these parameters in medicine is partly a reflection of their relative ease of measurement using noninvasive techniques. Although arterial blood pressure varies according to where it is measured in the arterial tree, it is most commonly assessed in the brachial artery, which runs through the upper region of the arm. Two commonly employed measurement techniques, auscultatory and oscillometric, employ an occlusion cuff that contains an inflatable bladder applying pressure through the arm to first interrupt and then progressively restore blood flow through the brachial artery.

With the auscultatory method, a stethoscope or microphone is positioned over the brachial artery, distal to the occlusion cuff. When the pressure in the occlusion cuff is above systolic pressure, the brachial artery is compressed and no sounds are detected distal to the cuff. When the slowly deflating occlusion cuff drops below the systolic pressure, the compressed artery opens momentarily and the brief episode of turbulent blood flow distal to the cuff is detected as a faint tapping sound; the first phase I Korotkoff sound is used to indicate systolic blood pressure. As the cuff pressure continues to fall, the Korotkoff sounds increase in intensity and quality, followed by a muffling of the sound (phase IV) and ultimately their disappearance (phase V). Diastolic pressure is usually defined as phase V in adults, while in children phase IV may be a closer approximation. With the auscultatory technique, mean arterial pressure cannot be

measured directly, but may be estimated as diastolic pressure plus one-third of the pulse pressure.

The oscillometric method also employs the occlusion cuff in a manner similar to that for auscultatory measurement. However, with the oscillometric technique, cuff pressure oscillations coincident with pulsatile pressure variations in the artery form the basis of blood pressure measurement. As the occlusion cuff is deflated, systolic pressure is indicated by a sharp rise in cuff pressure oscillations. The lowest pressure at which the cuff oscillations are at their greatest amplitude identifies mean arterial pressure. Diastolic pressure is recorded as the point at which the cuff pressure oscillations decrease no further in amplitude.

The auscultatory and oscillometric methods are by far the most widely utilized methods for measuring blood pressure. One of their limitations is that because they use a slowly deflating occlusion cuff, blood pressure measurements are limited in frequency to approximately once per minute. Other techniques include direct arterial pressure recording via a pressure transducer on the tip of an intra-arterial catheter, a method often employed to monitor vital signs during major surgery. One advantage of this invasive method is that it provides a continuous measurement of blood pressure on a beat-by-beat basis. A number of research-orientated techniques, including cuff tracking, vascular unloading, arterial tonometry, and pulse transit time, provide methods to assess blood pressure beat by beat, yet noninvasively, each offering specific strengths and limitations. All of the methods described above have been employed in studies examining the effects of stress on blood pressure.

Hypertension

Hypertension is defined as systolic blood pressure of 140 mmHg or greater, and/or diastolic blood pressure of 90 mmHg or greater. These criteria, based on seated clinic blood pressure measurements, are recognized by the World Health Organization/International Society of Hypertension and the United States Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC). Pressures in excess of 140/90 mmHg are further categorized in terms of severity of hypertension, currently defined as stages 1 and 2 (JNC VII). While blood pressures less than 140/90 mmHg were once considered normal, the JNC VII report now classifies blood pressures in the range 120–139/80–89 mmHg as prehypertension. This new category reflects a growing recognition that the clinical criteria for hypertension are somewhat arbitrary, and that cardiovascular morbidity associated with high blood pressure is more of a

progressive phenomenon than one associated with a specific pressure threshold that engenders a sudden rise in health risk. The term prehypertension also signifies that individuals with pressures in this range are at greater risk of developing hypertension than individuals with lower pressures. Only pressures below 120/80 mmHg are considered optimal.

Prevalence of hypertension is related to age, race, and gender. Hypertension incidence is higher in Blacks than in Whites, particularly in the United States. In young to middle-aged adults, prevalence is much greater in males than females, while incidence increases quite dramatically in women after menopause. Though hypertension is defined by elevation of arterial blood pressure, its clinical significance is derived from morbid events affecting the heart, brain, and kidneys. Complications such as myocardial infarction and stroke are not directly due to elevated pressures, but to the resulting structural changes in the heart and blood vessels. One of the structural consequences of hypertension, hypertrophy of the left ventricle (LVH), is the strongest known predictor, other than advancing age, of cardiovascular morbidity and mortality.

Hypertension is a disease that typically develops over years or decades, and in approximately 90% of cases it is diagnosed as primary (or essential) hypertension, indicating nonspecific etiology. The natural history of hypertension not only is characterized by a progressive increase in blood pressure, but also is accompanied by a progressive rise in systemic vascular resistance (SVR). The structural autoregulation theory of hypertension, originated by Folkow, helps explain why hypertension becomes a disease of elevated SVR. Arterial resistance vessels (arterioles) serve to regulate blood flow in accordance with local tissue demands. Vascular smooth muscle hypertrophy occurs as a physiological adaptation to increased blood pressure, which allows the vessel to maintain its ability to regulate blood flow at higher pressures. However, a consequence of this restructuring of the vessel is that it creates a rise in SVR, which increasingly provides the basis for the hypertension. Thus, structural autoregulation is a cascading pathophysiological adaptation. However, the unresolved question is what causes an individual's pressure to initially rise from normotensive levels, allowing the onset of pathophysiological processes. The answer to this question is likely multiple interacting factors, which vary across individuals, as reflected in Page's Mosaic Theory of hypertension. However, there is overwhelming evidence that the sympathetic nervous system is frequently implicated in the early stages of hypertension. In some, though not all, instances, this may give rise to a hyperkinetic circulatory state in which blood

pressure elevations are due to abnormally high cardiac output (CO) levels. It is the potentially pathophysiological effects of the sympathetic nervous system that suggest that stress may be implicated in the etiology of hypertension.

Stress and Blood Pressure

Psychophysiology of Stress

The impact of emotions and stress on blood pressure were recognized as early as the seventeenth century, as reflected in William Harvey's studies of the circulation. However, it was not until the twentieth century that the psychophysiological mechanisms by which stress influenced blood pressure became better understood. In 1915, Walter Cannon proposed that the sympathetic nervous system served to mobilize the cardiovascular system in preparation for fight or flight by engendering an increase in blood pressure and blood flow to the skeletal muscle vasculature. In the 1940s, the work of Hess identified the defense response, which was characterized by an integrative behavioral and cardiovascular activation pattern in response to electrical stimulation of the hypothalamus. This early animal research set the groundwork for our conception of the stress response as a psychophysiological phenomenon that primes the body in anticipation of recourse to sudden physical exertion.

In the latter half of the twentieth century, human research on the effects of stress on blood pressure was dominated by what has been termed cardiovascular reactivity studies, in which a variety of cardiovascular measures are recorded while volunteers are subjected to psychologically challenging tasks in a research laboratory setting. One of the earliest human studies was reported by Brod and colleagues in 1959, describing detailed cardiovascular response patterns observed while participants performed a stressful mental arithmetic task. Responses typically paralleled those of the animal defense response, with increased blood pressure and circulatory mobilization that occurred in the absence of significant metabolic demands. Essentially the same approach used by Brod has since been utilized extensively, and has led to the documentation of responses to a wide variety of laboratory stressors, including reaction time tasks, Stroop color-word conflict tasks, cold pressor tasks, simulated public speaking, and a variety of psychomotor tasks. One of the consistently striking observations from these studies is the individual differences in the magnitude of blood pressure responses: while at one extreme some individuals may show essentially no change in blood pressure, others may respond with an increase of

50 mmHg or more to exactly the same laboratory stressor. There is compelling evidence that these individual differences in blood pressure reactivity to stress are relatively robust, exhibiting consistency across a variety of laboratory tasks, and showing stability over time.

Blood pressure alone provides a limited picture of the hemodynamic pattern of changes elicited by stress. Hemodynamic studies emphasize the interrelationships among blood pressure, CO, and SVR. Since blood pressure is the product of CO and SVR, the concurrent measurement of blood pressure and CO permits the derivation of SVR, providing a more complete description of the hemodynamic response. Two very early stress studies conducted in the 1940s used invasive procedures to measure CO and, moreover, considered the measurement procedures themselves as presenting the source of psychological stress. These studies demonstrated how the stress response associated with anxiety was characterized by a mobilization of the cardiovascular system, leading to blood pressure increases due to an increase in CO. The same response pattern to a mental arithmetic task was observed over a decade later by Brod. In this classic study, CO was measured invasively using dye dilution, and forearm blood flow was also measured, leading to the demonstration that the increased CO during psychological stress appeared to be distributed to the skeletal muscle vasculature. These studies demonstrated that the fight-or-flight response, previously observed in animals, could be elicited in humans by psychological stressors.

With the development of noninvasive methods to measure cardiac output unobtrusively, in the past two decades there has been a resurgence of laboratory studies of the hemodynamic aspects of the stress response. These studies have consistently illustrated that there are dramatic individual differences in the hemodynamic patterns underlying blood pressure increases during stress. Thus, apparently similar cardiovascular responses to a stressor in terms of blood pressure change may belie very different underlying hemodynamic mechanisms. While some individuals exhibit blood pressure increases during stress due to an increase in CO and a decrease in SVR (fight-or-flight response), others may vasoconstrict, leading to an increase in blood pressure due entirely to increased SVR. Observations of this kind have led to an extension of descriptive categories in cardiovascular reactivity research, from high vs. low or hot vs. cold reactors, referring to the magnitude of blood pressure responses, to myocardial and vascular reactors, referring to the hemodynamic mechanism producing the blood pressure response. The mechanisms and potential health consequences of these individual differences are currently under exploration.

Stress and Hypertension

Although acute stress can indisputably raise blood pressure for brief periods into the range defining hypertension, its role in the etiology of sustained hypertension remains controversial.

Observational studies of stress reactivity There is some evidence that risk of hypertension development may be related to stress reactivity. Hypertensive individuals have been found to show greater blood pressure reactivity than normotensives. Individuals with normal blood pressure who have hypertensive parents also typically exhibit greater blood pressure reactivity to laboratory stressors than normotensives with no family history. Whereas studies describing only observations of the magnitude of blood pressure responses have reported inconsistent findings for the effects of race, a number of studies have reported that Black men, who are at increased risk for hypertension, appear to exhibit abnormally elevated vascular tone, indexed by SVR, during exposure to a variety of laboratory stressors. Gender differences in reactivity have also been observed, with men exhibiting greater systolic blood pressure and SVR increases than premenopausal women. These gender differences in SVR response are consistent with those observed for race in that men are more likely to develop hypertension than premenopausal women.

Since hypertension is a disease whose natural history involves progressively increasing blood pressure, which in turn is secondary to progressively increasing SVR, the tendency for individuals at greater risk for developing hypertension to exhibit pronounced stress-induced blood pressure and/or SVR reactivity is provocative. Reactivity studies have also demonstrated that stress can modify renal function, leading to sodium and fluid retention in some individuals, which may heighten and prolong stress-induced blood pressure elevations; altered renal function may be one of the target organ effects of stress that could impact long-term blood regulation. Additionally, several recent studies have reported an association between blood pressure reactivity and LVH, whereby the magnitude of blood pressure response during stress is directly related to LV mass.

Prospective studies of stress reactivity Although correlational evidence of the kind described previously is provocative, it is inconclusive since it does not rule out the possibility that associations of stress reactivity to hypertension risk and/or end organ damage may simply be a manifestation of underlying pathophysiology; the stress response may be a marker rather than a mechanism of disease. Prospective

studies should help resolve these cause–effect limitations by focusing on the temporal relationship of the correlated observations. As previously noted, hypertensive individuals are characterized by blood pressure hyperactivity, but is blood pressure hyperactivity in normotensives associated with the subsequent development of hypertension? Evidence relating to this question comes both from human and animal studies.

Animal studies In 1969, Forsyth described the effects of prolonged daily exposure to unsignaled shock avoidance schedules in rhesus monkeys. After several months, three of four animals developed hypertension. However, these findings were not replicated in other species. Beginning in the 1970s, a series of elegant studies was reported by Henry and colleagues on the effects of chronic social conflict in mice. When reared in isolation and subsequently transferred to colonies that made social conflict unavoidable, hypertension developed after several months, suggesting that chronic social stress could be a cause of hypertension. However, subsequent studies in other species were again less definitive. The importance of genetic susceptibility was demonstrated by Lawler's 1980s studies of borderline hypertensive rats, which developed hypertension when exposed to prolonged aversive reinforcement contingencies, whereas control animals typically remained normotensive. Other studies have suggested that the development of hypertension in salt-sensitive strains of animals of various species is exacerbated by exposure to stressful behavioral paradigms. In summary, the animal studies suggest that stress may play a role in the development of hypertension, but its impact is only likely to be important in the context of a pre-existing disposition to develop the disease.

Human studies There has been much interest in the possibility that individuals characterized by unusually large magnitude blood pressure reactivity may be at increased risk for the development of hypertension. Several studies have generated indirect support for the so-called stress reactivity hypothesis. In an early study of White males, blood pressure reactivity in response to a hand cold pressor task was examined as a predictor of the development of hypertension at 20- and 36-year follow-up. The study revealed that subjects in the top quartile of systolic blood pressure reactivity had a greater incidence of hypertension from age 40 onward, compared to the less reactive subjects. Other relatively long-term follow-up studies have shown the cold pressor task to predict the development of elevated blood pressure. One criticism of these studies is that the cold pressor may not be a

purely behavioral stressor, since it is a painful stimulus for most individuals; although, in common with other laboratory behavioral stress tasks, its cardiovascular effects are mediated primarily by sympathetic nervous system activation.

Blood pressure reactivity to a reaction time task involving threat of shock was found by Light and colleagues to predict increases in blood pressure 10 to 15 years later. High levels of systolic blood pressure during the reaction time task were associated with higher clinic and ambulatory systolic pressure at follow-up, even after controlling for parental history of hypertension and baseline resting systolic and diastolic blood pressure. Several studies in adolescents and young adults examining reactivity to mental arithmetic as a predictor of hypertension have also found evidence that high blood pressure reactivity and/or delayed recovery of the stress-induced blood pressure response predicts the development of hypertension at follow-up 1–5 years later. Other studies have made similar observations based on initial reactivity assessments using video games, Stropp color-word conflict, and mirror trace tasks. The studies reported to date are inconsistent in whether systolic blood pressure reactivity, diastolic blood pressure reactivity, or both is predictive of hypertension development. This discrepancy may also reflect differences in the population sample being studied, as well as differences in the nature of the blood pressure response associated with the specific stressor employed in a given study. It is also of note that the degree to which reactivity has predicted the development of high pressure or hypertension has been generally modest. As suggested by the animal studies, genetic susceptibility (i.e., family history of hypertension) is likely to be an important determinant of hypertension development, but was not considered in all of the reactivity studies. Furthermore, if stress reactivity is viewed as a disease mechanism, then the predictive value of high reactivity is likely to be largely moderated by the extent to which repeated acute stress responses occur in the time interval from assessment to follow-up. Assessing the frequency of stress responses over the long term presents a methodological challenge that has yet to be met in reactivity studies.

Psychosocial factors and hypertension Relatively few prospective studies have examined the relationship of psychosocial factors to the subsequent development of hypertension. The Framingham Heart Study examined the role of anxiety, anger intensity, and anger suppression in normotensive men. After controlling for biological risk factors, anxiety at baseline remained an independent predictor of hypertension in middle-aged men. The National Health

and Nutrition Examination Survey I Epidemiologic Follow-up Study also followed several thousand initially normotensive individuals for 7 to 16 years to test the hypothesis that symptoms of anxiety and depression increased the risk of developing hypertension. High anxiety and depression were independent predictors of incident hypertension ($\geq 160/95$ mmHg) in White men aged 45 to 64 years and Black men aged 25 to 64 years. In a large prospective study in Alameda County, California, unemployment, job insecurity, and concerns over job performance in men and low-status work in women were associated with increased likelihood of developing hypertension, after controlling for demographic and behavioral risk factors. Finally, several smaller correlational and prospective studies have found a significant relationship between the personality trait defensiveness and hypertension.

Studies of chronic stress Studies of environments that may engender chronic states of stress also provide a test of the effects of stress on blood pressure. In a study of individuals residing near the Three Mile Island nuclear power plant, blood pressure was found to rise shortly after the 1979 accident in which part of the facility was destroyed. Blood pressure remained elevated for 5 years and was associated with increased sympathetic nervous system activity compared to individuals residing further from the nuclear plant. Studies of prisoners also suggest that living in overcrowded conditions is associated with elevated blood pressure. Occupations considered to be associated with chronic stress include air traffic controllers, who have been found to show a much greater incidence of hypertension than workers in comparable, but less stressful, occupations. A relationship between occupational stress and elevated blood pressure and/or hypertension is supported by other studies, including those utilizing ambulatory blood pressure measurement technology to measure blood pressure in the working environment.

Ambulatory Blood Pressure

Methodology

Advances in computer and miniaturization technology over the past 25 years have aided the development of wearable ambulatory blood pressure (ABP) monitors. ABP monitors are able to capture the normal activities and environmental interactions during the course of an individual's day. Utilizing common blood pressure measurement techniques, ABP monitors permit frequent noninvasive blood pressure recordings based upon auscultatory and/or oscillometric measurement principles. ABP monitors are typically programmed to take blood pressure measurements

several times per hour, at variable intervals, throughout the workday, evening, and overnight. Individuals are ordinarily instructed to follow a normal schedule during waking hours and to complete a brief diary immediately following each reading indicating factors such as time, posture, activity, location, and current emotional/cognitive state. Factors such as posture and physical activity have been shown to systematically influence blood pressure. Location and emotional state have also been found to affect blood pressure, but the magnitude of their effects varies greatly from individual to individual. Finally, recent research suggests that the degree of familiarity with a conversant as well as the positiveness or negativeness of the interpersonal interaction affects ABP levels.

White Coat Hypertension

Because morbid events are often associated with hypertension, blood pressure is routinely measured during visits to a physician's office. However, psychological stress associated with visiting a doctor's office can spuriously inflate clinic blood pressures in some patients. Individuals whose blood pressures are in the hypertensive range when measured in the clinic but are normal in other contexts, as indicated by ABP measurements and/or automated home measurements, are classified as white coat hypertensives. Studies suggest that when compared to sustained hypertensives, white coat hypertensives are more likely to be younger female nonsmokers with a lower body mass index. Although most studies have found no association between psychological factors and white coat hypertension, there is some evidence that anxiety may be a related characteristic. Multiple ABP measurements throughout the day are thought to be more representative than clinic measures of the overall load that is placed on the cardiovascular system. Thus, 24-h ABP recordings can provide important supplementation of clinic readings in the accurate diagnosis of hypertension and are more closely correlated with end organ damage, including left ventricular mass, than clinic blood pressure.

Emotional States, Psychosocial Characteristics, and ABP

ABP monitoring is particularly well suited for capturing acute affective states that occur in response to daily stress. Several studies have indicated that emotions, as indicated by diary ratings of moods, influence ABP levels. Both negative and positive moods have been found to be associated with increased ABP. However, a great deal of individual variability in the reporting of diary-rated moods has been observed, suggesting that certain individuals may be more

susceptible to experiencing emotional upset throughout the day. Similarly, the effects of emotions on ABP are more pronounced in some individuals than in others. Nonetheless, studies indicate that for diary ratings of negative emotions, including stress, frustration, and tension, greater emotional intensity is accompanied by higher ABP.

There is some evidence that psychosocial characteristics that are risk factors for cardiovascular disease, including anxiety, depression, and lack of social support, are associated with greater fluctuations in diary ratings of negative moods; these individuals have also been found to exhibit a greater impact of emotion on ABP. There is also evidence to suggest that negative emotional dispositions, such as hostility, may have an impact on ABP, but only in certain social contexts. While recent studies indicate that dispositional characteristics (e.g., defensiveness and pessimism), coping responses (e.g., religious coping), and reactions to racial inequality (e.g., perceived racism) may be associated with ABP levels, these preliminary findings would benefit from further replication.

ABP and Location

Work If a 24-h day is divided into work, home, and overnight periods, most people's blood pressure will be highest during work, lower while at home, and lowest during the overnight period. However, these locational effects on blood pressure vary greatly from one individual to the next. This suggests that location per se is not directly associated with blood pressure, but rather that location is associated with a variety of behavioral factors (e.g., activity level, posture) and psychosocial factors (e.g., mood, social support, negative interpersonal exchanges, stress) that under certain circumstances may influence blood pressure. ABP studies conducted on individuals across a variety of occupations (e.g., paramedics, physicians, clerical personnel) indicate that perceived or actual occupational stress does, in fact, increase ABP levels. These associations have prompted researchers to examine specific job characteristics that might contribute to elevations in blood pressure across a variety of occupations. One model of job characteristics that contributes to work-related stress is Karasek and Theorell's job strain model. Karasek and Theorell maintain that a deleterious combination of high psychological job demands and low decision latitude at work results in a condition of job strain. Numerous studies have found that higher levels of job strain are associated with higher blood pressure, particularly in men. There is also evidence that job strain is associated with increased LV mass, which may be a consequence of ABP effects.

Home Behavioral and psychosocial influences on ABP at home are likely to be very different from behavioral and psychosocial influences at work. The home environment may be influenced by factors such as the quality of familial relationships and their ability to provide social support, the level of domestic and family responsibilities, and the existence of role conflict or dissatisfaction. Although research on the home environment and ABP is sparse, one study that examined blood pressure in working women found that married working women had higher ABP than unmarried working women. These findings suggest that, compared to unmarried working women, the higher ABP levels found in married working women may reflect their greater combined work and home responsibilities, possibly suggesting a total greater workload. Elevated ABP in the home environment may also be associated with home stress, making it more difficult to unwind, both psychologically and physiologically, after work.

Sleep Blood pressure typically falls during nighttime sleep. Most individuals are characterized by >10% fall in nighttime blood pressure and are referred to as dippers, in contrast to non-dippers, who exhibit <10% nighttime blood pressure fall. Sleep blood pressures may be influenced, at least in part, by events that occur during waking hours. Studies have found that the daily experience of negative moods on blood pressure appears to carry over from daytime waking to nighttime sleep. Individuals that frequently report anger during the day tend to have higher levels of blood pressure, especially during sleep. There has been some speculation that unresolved stressful experiences and negative mood states that occur during the day might contribute to disrupted sleep patterns, a diminished quality of sleep, or somatic tension that influences blood pressure levels. In addition, a positive family history of hypertension, low socioeconomic status, and African American ethnicity have been associated with blunted nocturnal blood pressure dipping. Dietary factors, including high sodium consumption and low potassium consumption, also have been related to blunted nighttime blood pressure dipping. Sympathetic nervous system activity also appears to be an important factor, with nighttime catecholamine levels and vascular adrenergic receptor activity also appearing to play a role in nocturnal blood pressure dipping. The magnitude of nocturnal decline in blood pressure has been found to relate to LV mass, with non-dippersexhibiting elevated LV mass and higher likelihood of LVH compared to dippers. This evidence underscores the importance of studying nighttime blood pressures and its possibly complex biopsychosocial determinants.

Disturbances in Endogenous Stressors

Disturbances in Exogenous Stressors

Implications and Clinical Correlations

Glossary

<i>Blood–brain barrier</i>	The interface between circulating blood and brain interstitium.
<i>Hypoxia</i>	Deficiency in the amount of oxygen reaching body tissues.
<i>Ischemia</i>	Cessation of blood flow with subsequent deprivation of glucose and oxygen delivery to the tissue.
<i>Neuroinflammation</i>	The activation of the innate inflammatory cascade within the brain parenchyma in response to various insults, cellular damage, and inflammatory molecules.
<i>Neurovascular unit</i>	The histological structure and function forming the blood–brain barrier.
<i>Tight junctions</i>	Protein complexes located at the apical portion of the cell that associate with homologous structures on the adjacent cell to seal the gap between the cells.

Structure and Function

The blood–brain barrier (BBB) serves as an interface between circulating blood and the brain interstitium. Histologically, the BBB corresponds to the neurovascular unit (**Figure 1**), a highly specialized structure composed of specialized brain capillary endothelial cells, astrocytes and astrocyte processes, pericytes, neuronal terminals, and occasional microglial cells. The brain capillary endothelial cells line the interior of the neurovascular unit and differ from systemic endothelial cells by having rare pinocytotic vesicles and absent fenestrations. Thus, the main gap in the barrier is the space between the cells. These endothelial cells have extensive tight junctions that seal the gap to form the barrier and are held together by strong adherence junctions. Tight junctions are located at the apical portion of the cell and are composed of transmembrane proteins such as occludin, claudins and junctional associated proteins, and intracytoplasmic proteins such as zonula occludens and other proteins that bridge the tight junctions to actin and other proteins of the cytoskeleton. The cells of the neurovascular unit express various transporters that regulate the flux of glucose and other nutrients, metabolites, water, sodium, potassium, and other substances into and out of the brain parenchyma. The BBB also isolates the brain tissues from blood constituents and drugs that could alter neuronal function and provides a large surface area by which the brain

can sense alteration in the circulation supplying its various structures. Proper functioning of the BBB is essential to maintain homeostasis of the central nervous system (CNS). Disruption of BBB integrity and alterations in its structure and constitution mediate the pathophysiology of a wide range of CNS disorders and the neurological sequelae of many systemic diseases. The BBB can respond to and be influenced by alterations in the internal and external conditions of the human body as well. This article reviews the pathology of the BBB in various disturbances and stressors intrinsic and extrinsic to the CNS.

Disturbances in Endogenous Stressors

Infection and Inflammation

The BBB integrity and permeability are influenced to a great extent by systemic and local inflammatory mediators acting on the various elements of the neurovascular unit. It has been shown in many experimental models that there is a breakdown in BBB with increased permeability to proteins in conditions of systemic inflammation. These effects are mediated by direct exposure and binding of circulating inflammatory ligands (e.g., lipopolysaccharide) by Toll-like receptors, and of circulating cytokines

(e.g., interleukin-1 and tumor necrosis factor- α) and activated complement proteins to their receptors at the BBB and other specialized structures such as the circumventricular organs and the choroid plexus. In addition, increased local production of these factors within the brain parenchyma causes similar effects.

When molecules of the inflammatory cascade bind to their respective response elements on the BBB, nuclear factor- $\kappa\beta$ and other inflammatory pathways are induced in the endothelial cells. In addition, other cellular constituents of the neurovascular unit are activated, which induce the activation of nitric oxide synthase (iNOS), cyclooxygenases that release prostanooids, free radicals, histamines, bradykinins, vascular endothelial growth factor, and other paracrine factors. These factors in concert serve to further propagate the inflammatory wave across the BBB and into the brain parenchyma. Propagation of these inflammatory waves also upregulates local matrix metalloproteases (e.g., MMP-9), which will further disrupt the extracellular matrix supporting the structure of the neurovascular unit and the blood vessels in the brain. Cell adhesion molecule (e.g., ICAM-1, VCAM, MCP-1) expression is also increased on endothelial cells. These molecules bind to the endothelial cells and facilitate the trafficking of inflammatory cell across the BBB into the brain parenchyma potentiating the ongoing inflammatory cycles. Increases in P-glycoprotein expression and other molecules also control the transport of inflammatory related substances across the BBB.

The expression, localization, and interaction of proteins that form the tight junctions between endothelial cells of the BBB are altered and disrupted during the inflammatory process described previously. This process serves to weaken the integrity of the BBB and increase the permeability of the barrier to cells, proteins, and smaller molecules normally present in the systemic circulation that would otherwise be excluded from the brain parenchyma by an intact BBB under physiological conditions. The resultant disturbances in CNS homeostasis contribute to the pathophysiology of a number of disease processes affecting the CNS.

Chronic local inflammatory pain in peripheral organs has been associated with increased cell adhesion molecule expression, microglial activation, alterations in tight junction proteins, and increased BBB permeability. These alterations in the BBB are thought to mediate some neurological manifestations of chronic fatigue syndrome and other rheumatic conditions.

Microorganisms can cause systemic illness and, consequently, induce the cascade of inflammatory events described previously. Further, many microorganisms have the ability to gain access into the brain parenchyma by translocating through the BBB.

Bacteria (e.g., group B streptococcus, *Escherichia coli*) viruses (HIV), yeast, and prions utilize many of the mechanisms and molecules described previously for inflammation in order to cross the BBB and gain access to the brain. Circumventing the BBB by neurotrophic lentiviral vectors is a major area of interest for gene delivery models in modern neuroscience.

The mechanisms of BBB alteration described for inflammatory conditions are basic not only to inflammatory diseases of the CNS, but also to the pathophysiological processes that underlie brain injury in hypoxia, ischemia, oxidative stress, trauma, tumors, and many other CNS disorders.

Hypoxia/Ischemia Reperfusion Injury

Hypoxia/reoxygenation and ischemia/reperfusion injury alter the permeability and structural properties of the BBB. A large number of *in vitro*, *in vivo*, and magnetic resonance imaging (MRI) studies have documented increased BBB permeability and compromised structural BBB integrity under hypoxic conditions. Both hypoxic and ischemic conditions induce alterations in the expression and localization of a variety of key tight junction proteins, glucose and nutrient transporters, water and electrolyte transporters, and increase in nonspecific transport of blood-borne proteins into the brain parenchyma.

Mechanisms underlying these changes in permeability and structure of the BBB involve the simultaneous activation of a number of second messenger systems that mediate the consequences of hypoxia/reoxygenation, and ischemia/reperfusion injury on the BBB. These include the increases in hypoxia inducible factor, vascular endothelial growth factor, nitric oxide, and the activation of protein kinase C, nuclear factor- $\kappa\beta$, adenylate cyclase, and intracellular calcium pathways. These mechanisms include direct effects of oxygen toxicity and metabolite deprivation, production of oxygen free radicals, cessation of shear blood flow with static leukocytes adhering to the blood vessel walls and invading the neurovascular unit, and the induction of local inflammatory cascades. Local and leukocyte-derived MMP-9 activation mediates BBB breakdown after transient focal cerebral ischemia. During thrombolytic treatment of human stroke and the resulting reperfusion, lipoprotein receptor-mediated induction of MMP by tissue plasminogen activators can predispose a patient to hemorrhagic complications. Higher MMP-9 pretreatment levels have been shown to correlate with more severe hemorrhagic complications after thrombolysis. Biochemical markers of BBB dysfunction and brain ischemia such as elevated S100B values have been shown to be powerful predictors of a poor prognosis for neurological outcomes after cardiac surgery,

particularly when elevated levels are associated with other CNS complications.

Hypercapnia and Acidosis

Markers of BBB permeability are increased in the brain parenchyma and cerebrospinal fluid (CSF) under conditions of severe hypercapnia. Hypercapnia-related increases in bilirubin deposition results from increased BBB permeability for bilirubin and is one of the mechanisms by which hypercapnia can predispose newborn subjects to CNS bilirubin toxicity. Other mechanisms include the accumulation of these markers in the brain because decreases in CSF secretion during prolonged hypercapnia could limit the removal of the substances from the CNS via the CSF route. Elevated carbon dioxide levels and the direct effects of acidosis can increase the barrier permeability to molecules in the systemic circulation, which normally are excluded by the intact BBB from the CNS. At relatively low pHs, the resulting changes in the ionic milieu can alter the negatively charged endothelial cell surface sialoglycoproteins and glycolipids, which are integral parts of the BBB. Changes in blood carbon dioxide concentrations, hydrogen ion, and bicarbonate contents also may alter the expression and activity of H^+ -ATPase, Na^+/H^+ exchanger, a ubiquitous plasma membrane transport system, and other ion exchangers, which normally regulate the cytoplasmic pH in the cells of the BBB. Such changes in the composition of the BBB contribute to the pathophysiology of acid-base-related disturbances in the CNS.

Osmotic Stress

Exposure to hyperosmotic conditions can disrupt the tightness and integrity of the BBB. Osmotic opening of the BBB is potentially reversible upon cessation of the osmotic stress. Reversible osmotic disruption and reconstitution of the BBB may be due not only to simple mechanical shrinkage of the endothelial cells but also to intracellular Ca^{2+} -activated mechanisms. *In vitro* studies have shown that intracellular Ca^{2+} concentrations increase rapidly, and values peak within 10 s after the application of mannitol and return to the basal levels within 200 s. A specific Na^+/Ca^{2+} exchanger mediates the reconstitution of the BBB at the cellular level. Considering the usefulness of reversible opening for delivery of chemotherapeutic agents across the BBB, manipulations of this exchanger by selective inhibitors may have clinical implications in prolonging the opening phase of the capillary endothelial cells for more efficient drug delivery into the CNS.

During chronic hypertonic conditions such as severe hypernatremia, cells accumulate intracellular

organic osmolytes to equilibrate the osmotic gradients. Rapid reduction of extracellular hypertonicity predisposes these cells to excessive swelling and edema. Circulating ions and osmolytes equilibrate slowly across the BBB, and rapid decreases in plasma osmolality can cause major brain fluid shifts resulting in edema and severe cerebral lesions. Rapid correction of chronic hyponatremia can cause osmotic-induced demyelination of the brain. An intact BBB protects oligodendrocytes to a certain extent from the direct exposure to osmotic imbalances. However, disruption of the BBB during an osmotic stress results in massive damage to oligodendrocytes with subsequent development of demyelinating lesions in the brain.

The ability of the brain to exhibit volume regulation when subjected to osmotic stress develops in a region- and age-related fashion. In ovine fetuses, brain volume regulation develops first in the cerebral cortex at 90% of gestation and in the cerebral cortex and cerebellum of newborn lambs, and then it develops in the medulla of the lambs at 20–30 days of age. Therefore, in young subjects, the adverse effects of hyperosmotic stress may vary in an age- and region-specific manner.

Diabetes

The effects of long-standing diabetes on BBB permeability and integrity are region specific and variable. MRI studies in well-controlled diabetics showed increases in signal intensity in the basal ganglia with contrast infusion, indicating increased permeability of the BBB in basal ganglia compared to controls. Other studies suggest that chronic hyperglycemia may induce vascular endothelial growth factor production by glial cells at the blood-retinal barrier. This alters the expression of tight junction proteins such as occludin and ZO-1, and consequently increases capillary endothelial permeability that predisposes to the edema formation in diabetic maculopathy. In contrast, BBB permeability and tight junction protein expression were not altered in the cerebral cortex of diabetic patients. Chronic hyperglycemia decreases the number of glucose transporters available at the BBB. The primary mechanism underlying this downregulation is a posttranscriptional inhibition of glucose transporter mRNA translation. Such an adaptation could decrease the net flux of glucose into the brain during sustained hyperglycemia. The downregulation of glucose transporters during chronic hyperglycemia also contributes to the alarming sensitivity to hypoglycemia in diabetic patients. Diabetic ketoacidosis is associated with a life-threatening development of cerebral edema immediately after the recovery from ketoacidosis. Accumulation of weak acids such as ketoacids and free fatty acids in the cytoplasm of brain cells lowers the intracellular pH,

resulting in activation of the Na^+/H^+ exchanger, leading to cellular swelling and cerebral edema.

Hypertension

Studies on the effects of chronic hypertension on BBB permeability indicate a regional predilection for CNS lesions compared with permeability under normotensive conditions. Focal increases in the rate of BBB transfer for small molecules have been reported to increase up to two to seven times the normal rate of transfer. Particularly susceptible regions include the hippocampus, hypothalamus, blood-retinal barrier, and the blood-CSF barrier at the choroid plexus. Acute hypertensive crises have been associated with disruptions in the BBB integrity, when systolic blood pressures reach a certain threshold, or when the BBB has been weakened by other conditions such as in diabetes. These disruptions in the BBB during acute hypertension are more pronounced to neutrally charged molecules than to negatively charged molecules.

Disturbances in Exogenous Stressors

Smoking

Smoking is one of the major risk factors for stroke in humans. *In vitro* stroke models studying bovine brain microvessel endothelial cell cultures under hypoxic/aglycemic conditions demonstrated that BBB K^+ transport mechanisms by the abluminal Na,K,2Cl -cotransporter are downregulated after exposure to nicotine and cotinine at concentrations comparable to plasma levels seen in smokers, and these changes could influence ischemic brain K^+ homeostasis in crucial times of neuronal recovery after stroke.

Alcohol

Alcohol increases BBB permeability in a dose-dependent fashion. Ethanol-induced activation of myosin light chain kinase (MLCK) in the endothelial cells of the BBB leads to phosphorylation of MLCK, occludin, and claudin-5 with resultant cytoskeletal alterations and tight junction changes that facilitate monocyte migration across the BBB. In addition, alcohol predisposes to oxidative stress in brain endothelial cells, causing BBB dysfunction and aggravation of neuroinflammatory disorders of the CNS.

Immobilization and Restraint Stress

Immobilization and restraint stress have been associated with increased BBB permeability in the hypothalamus, midbrain reticular formation, and the cerebellum. Activation of mast cells that preferentially populate these regions of the brain and possible activation of serotonergic pathways have been speculated

as possible mechanisms. The resultant oxidative stress and BBB breakdown have been associated with increased circulating levels of S100B protein. Interestingly, biting suppresses oxidative stress induced by restraint stress, and the antistress effect of masticatory motor activity movements, such as biting or chewing, may be important for reducing the adverse effects associated with exposure to psychological stressors.

Steroids

Exogenous corticosteroid administration has been shown to decrease BBB permeability in many *in vitro* and *in vivo* studies of adult and fetal models. Other studies suggest that corticosteroid administration promotes tightening of the BBB during adverse events such as focal cerebral ischemia. Glucocorticoids may act by suppressing inflammation and by directly affecting phosphorylation, organization, and upregulation of tight junction proteins in endothelial cells. However, glucocorticoids also can inhibit glucose transport in cultured hippocampal neurons and glia, and may reduce nutrient delivery to the brain during critical periods of hypoxia and ischemia. Pretreatment with antenatal dexamethasone did not reduce the extent of pathological brain injury following ischemia/reperfusion in an ovine fetal model. Estradiols have also been shown to attenuate BBB disruption induced by cerebral ischemia/reperfusion injury in female rats and to enhance brain glucose uptake by upregulation of glucose transporter-1 expression in the BBB. Thus, estradiols may have advantages over corticosteroids in this regard.

Endogenous corticosteroid production by the hypothalamic-pituitary-adrenocortical axis under stressful conditions, such as systemic inflammation and cerebral ischemia, provides an endogenous negative feedback loop to reduce the extent of ongoing neuroinflammation and BBB disruption secondary to these insults. Blocking this mechanism by corticosteroid antagonists markedly exaggerates the damage secondary to ischemic brain injury.

Thermal Stress: Hypothermia, Hyperthermia, and Ultrasound Waves

Hypothermia, when initiated early on, can attenuate the development of the BBB opening to various insults. In an ischemia/reperfusion model, whole body cooling to 31.5–32.5°C attenuated the increase in BBB permeability when cooling was initiated early during reperfusion. Hypothermia also has been effective in attenuating BBB disruption by hyperosmolar infusions. This suggests that there are direct effects of hypothermia on the elements of the neurovascular unit, in addition to its role in the reduction of

inflammatory cascades accompanying ischemia/reperfusion injury.

Hyperthermia has detrimental effects on ischemic infarct volumes both during and after the induction of ischemia. Many studies have found increases in BBB permeability along with disruptions in the integrity of tight junctions and decreased expression of ZO-1 after hyperthermia. The pathophysiology of hyperthermic brain injury and BBB disruption is complex, with many factors such as NOS, histamines, prostaglandins, and other pathways contributing to the hyperthermic-related injury. These changes are more pronounced in younger subjects than in adult subjects and may be implicated in the pathophysiology of febrile seizures in younger children.

Local opening of the BBB by mild hyperthermia induced by ultrasound waves is gaining interest as a novel approach to increase drug uptake in brain microvascular endothelial cells. High-intensity focused ultrasound is capable of reversible BBB disruption in a targeted region of interest by opening capillary endothelial cell tight junctions; this opening reverses after 72 h. Sometimes ultrasound-induced hyperthermia can damage tissues in a small volume within the region of BBB opening. Newer techniques are being studied to achieve local and reversible BBB disruption without damaging neurons by the use of non-invasive focused ultrasound at frequencies suitable for trans-skull sonications applied to cavitate special lipid-coated microbubbles within the cerebral microvasculature for delivery of both low- and high-molecular-weight therapeutic compounds to the brain.

Other Stressors

Effects of long-term mobile communication microwave exposure and electromagnetic radiation on the vascular permeability in the brain has been a public health concern. Current evidence suggest that most of the reported effects are negligible as long as the radiation intensity remains in the nonthermal range. BBB dysfunction has been speculated in the pathophysiology of high altitude cerebral edema and acute mountain sickness and diving and decompression sickness, probably due to circulatory microbubble-induced damage of the BBB.

BBB and Aging

Senescence is associated with changes in BBB function. Conditions associated with aging, such as hypertension and cerebrovascular ischemia, aggravate the age-related alterations in BBB function, and the barrier becomes more susceptible to disruption with aging. Such alterations appear to be region specific.

More profound changes have been associated with Alzheimer's disease, and the BBB is now thought to have an important role in this disorder. Common age-related changes in the neurovascular unit include loss of capillary endothelial cells, elongation of the remaining endothelial cells, decreased capillary diameter, and a decrease in the number of mitochondria in endothelial cells. The aging BBB shows alterations in carrier-mediated transport systems, including a decrease in transport of choline, glucose, butyrate, and triiodothyronine.

Implications and Clinical Correlations

BBB dysfunction plays a major role in the pathogenesis of a large number of neurological disorders including stroke, multiple sclerosis, Alzheimer's disease, Parkinson's disease, cerebral palsy, leukoencephalopathies, and cerebral hemorrhages. Impairment of BBB function contributes significantly to the neurological sequelae resulting from or associated with many systemic stresses and disorders. A thorough understanding of the pathophysiology of the BBB and of the factors influencing its structure, function, and integrity is essential for the development of targeted drug delivery strategies and safer and more effective therapies in the management of many diseases of the CNS.

Treatment of Borderline Personality Disorder

Glossary

<i>Neuro-transmitter</i>	One of a number of chemical substances which, when released at the terminal of one neuron and captured by a specialized receptor on the surface of another neuron, transmit a signal from one neuron to another.
<i>Personality</i>	Enduring patterns of perceiving, relating to, and thinking about the environment and oneself.
<i>Personality disorder</i>	The disturbance resulting from maladaptive personality traits which cause functional impairment or substantial distress.

Phenomenology and Epidemiology of Borderline Personality Disorder

Borderline personality disorder (BPD), a disorder characterized by emotional instability and impulsivity, is one of the more serious personality disorders. It is associated with high levels of distress, significant impairments in social and occupational functioning, and a risk of suicide approaching 10%. As a personality disorder, BPD reflects an enduring and inflexible maladaptation in an individual's characteristic pattern of perceiving, relating to, and thinking about the environment and self. In BPD, the individual is highly reactive to psychosocial events such as losses, separations, and frustrations. The individual with BPD may show intense but shifting extremes of emotion, often involving anger and depression. He or she may engage in impulsively self-destructive acts, or may recurrently threaten or attempt suicide. His or her relationships with others are typically intense and unstable, often oscillating between idealization and devaluation of others. By the same token, his/her own sense of identity is unstable and people with BPD are unsure of their goals, values, or sense of self. They may be terrified of real or imagined abandonment and may frantically attempt to control others to prevent this. Under the stress of losses, frustrations, or intense interpersonal relationships, individuals with BPD may regress, becoming more infantile or experiencing transient lapses in reality testing, which can

take the form of hallucinations or delusional ideas. They often experience a sense of boredom and inner emptiness. It is estimated that about 2% of the population meets criteria for BPD. It is more often diagnosed in women and is more common among first degree relatives of those with the disorder.

Role of Neurobiology

BPD appears to be the result of converging biological predispositions and early-life experience. Two biologically mediated dimensions of personality are particularly prominent in BPD, impulsive-aggression and affective instability. In borderline patients, the impulsive-aggression is most often self-directed, but it can also be directed to others. Impulsive-aggression has been shown to be associated with dysregulation in the serotonin neurotransmitter system. Cerebrospinal fluid levels of 5-hydroxyindoleacetic acid (5-HIAA), a breakdown product of serotonin, are inversely correlated with the degree of impulsive-aggressive and suicidal behavior in depressed patients and in patients with personality disorders. Borderline patients show a blunted response to the ingestion of fenfluramine, a serotonin-releasing and potentiating agent which triggers release of the hormone prolactin, and the degree of blunting in prolactin response to fenfluramine correlates with the level of impulsive-aggression manifest in the patient's life history. Studies, which use positron emission tomography (PET) scanning to show regional metabolic activity in the brain, have demonstrated that in BPD patients the response to the fenfluramine is diminished specifically in those brain regions responsible for inhibiting impulsive behaviors. Similar results were found using other serotonergic challenge agents.

The noradrenergic (norepinephrine) neurotransmitter system is also implicated in aggression in patients with personality disorders. Cerebrospinal fluid levels of 3-methoxy-4-hydrophenylglycol (MHPG), a norepinephrine breakdown product, have been shown to correlate positively with impulsive-aggressive behavior. The responsiveness of the noradrenergic system can be assayed by measuring the growth hormone response to clonidine. Growth hormone release in response to clonidine directly correlates with irritability. Since norepinephrine activity is associated with alertness, attention to external stimuli, and extraversion, it may be connected with outward-directed aggression. The interaction between serotonin and noradrenergic systems may determine the nature of aggression in BPD. Low serotonergic activity may predispose to impulsive aggression, which appears to be outward directed when noradrenergic activity

is high and inward directed when noradrenergic activity is low. Studies have suggested that the activity of another neurotransmitter, arginine vasopressin, may directly correlate with levels of aggression in personality disorders.

Affective instability may be associated with dysregulation of the neurotransmitter, acetylcholine. When borderline patients were given an acetylcholine-potentiating agent, physostigmine, they responded by becoming transiently more dysphoric for several minutes to 1 hour, whereas nonBPD patients did not show this reaction. The affective effect of physostigmine was associated with the patients' degree of affective instability, identity confusion, unstable relationships and feelings of emptiness and boredom, suggesting that these symptoms may all be related to affective instability.

Role of Life Experience

Early-life experience also appears to contribute to the development of BPD. Histories of repeated childhood physical or sexual abuse are commonly found among borderline patients, although such abuse experiences are also associated with a variety of other psychiatric disorders as well. Severe physical or emotional neglect may also predispose to BPD. Intense levels of aggressive drive, either resulting from an inborn predisposition or exceptionally powerful anger-inducing life experiences such as abuse, painful illness, or devastating losses, are also believed to contribute to borderline pathology. Some researchers have suggested that individuals who go on to develop borderline personalities have had impairments in their ability to evoke memories of their caretakers for use in soothing themselves in the absence of the caretaker. Other researchers emphasize the interaction of the affectively unstable child with a caretaking environment in which strong feelings are disavowed and the child is made to feel that his or her feelings are invalid.

Psychological Structures in the Borderline Patient

Psychoanalytic investigators have postulated that borderline individuals protect themselves from recognizing the consequences of their unacceptable feelings by developing inflexible and maladaptive defense mechanisms, such as splitting. Splitting is a defense in which the individual partitions his or her psychic experience into compartments which keep aggressive feelings away from images of loved and needed others. The partitioning of memory, which is the essence of splitting, may itself be a consequence

of the impact of affective instability upon emotion-state-dependent memory processes. Thus the use of splitting, with its associated anxiety-controlling effects, may derive from a psychobiological vulnerability to affective dysregulation. The extensive use of the splitting defense fragments the individual's internal images of self and others. This produces a confused sense of self and identity and contradictory pictures of others.

Treatment of Borderline Personality Disorder

Because of their ingrained nature, personality disorders are slow to change, and the impulsiveness and affective instability characteristic of BPD makes this disorder often difficult to treat. While no single treatment has been identified as the treatment of choice for BPD, patients have responded well to a number of psychotherapeutic approaches and to medications. Recent work has extended earlier observations that such anticonvulsant/mood-stabilizing medications as topiramate, divalproex sodium, lamotrigine, and carbamazepine can reduce anger, aggression, irritability, and impulsivity in borderline patients. Borderline patients also show a global positive response to the mood stabilizer, lithium carbonate. Monoamine oxidase (MAO) inhibitors, which affect several neurotransmitter systems, reduce depression, anxiety, hostility, self-destructiveness, and interpersonal sensitivity in BPD. Selective serotonin-reuptake inhibitor (SSRI) antidepressants have been shown to diminish hostility in borderline patients and may also reduce impulsive-aggression and depression. Low doses of antipsychotic medications have reduced the transient psychotic symptoms, hostility, impulsiveness, and, in some studies, depression in BPD. The newer atypical antipsychotic medications have been shown to reduce hostility, suspiciousness, paranoia, anxiety, and depressive symptoms in the disorder. At present, it remains an open question whether the beneficial effects of medication last beyond the 6–12-week periods examined in most studies. For patients with severe self-destructiveness and those who tend to be more action-oriented than introspective, a form of cognitive behavioral therapy, dialectical behavior therapy (DBT), has been shown to diminish self-destructive behavior and reduce the need for inpatient treatment. One recent study demonstrated that DBT in combination with the atypical antipsychotic medication, olanzapine, was more effective than DBT alone. Psychodynamic psychotherapies, which have helped

borderline patients develop an integrated sense of themselves and others and have led to enhanced interpersonal and career functioning, are suitable for patients who can contain dangerous behavior with the structure of an outpatient treatment contract and who are interested in identifying, understanding the origins of, and changing maladaptive interpersonal patterns. For some patients, sequential treatment with medication, DBT, and psychodynamic psychotherapy may be the optimal approach.

Introduction – Stress and the Brain

Brain Regions Concerned with Processing Stress-Related Information

Glossary

<i>Catecholamines</i>	Chemical signals (epinephrine, dopamine, and norepinephrine) synthesized from the amino acid tyrosine.
<i>Chromaffin cells</i>	Endocrine cells in the adrenal medulla that release adrenaline (primarily) into the blood on stimulation from sympathetic motor system.
<i>Diencephalon</i>	The part of the forebrain containing the thalamus and hypothalamus (including the preoptic area).
<i>Hypoglycemia</i>	Condition in which blood glucose concentrations fall below 60–75 mg dl ⁻¹ .
<i>Hypotension</i>	A reduction in blood pressure.
<i>Immediate early gene</i>	A gene whose product (usually a transcription factor) is rapidly produced as a consequence of receptor activation.
<i>Telencephalon</i>	The part of the forebrain containing the cortical regions (including the hippocampus), basal ganglia, bed nucleus of the stria terminalis, amygdala, and septal complex.

Introduction – Stress and the Brain

A wide variety of stimuli evoke motor events that are considered as stress responses. In simple organisms, these are made up of little more than sets of stereotyped reflexes. If the stressor is sufficiently intense or prolonged, these often consist of avoidance responses accompanied by endocrine-mediated alterations in metabolism. However, there is no evidence to suggest that invertebrates can associate emotional affect such as fear or anxiety with particular stressors. Only with the evolution of more complex central nervous systems (CNS) in general, and the telencephalon in particular, do we begin to see this type of associative processing.

In vertebrate species, stress is typically accompanied by endocrine secretions (e.g., from steroidogenic

tissue in the interrenal/adrenal glands), autonomic motor events (e.g., piloerection, increased secretion from the chromaffin cell/adrenal medulla system, and alterations in cardiovascular tone), sets of behavioral motor actions (e.g., avoidance responses, changes in defensive behavior, and fear-conditioned freezing), and those attendant emotional percepts generally recognized as being the most characteristic human signatures of stress (e.g., fear and anxiety). From a neural-systems perspective, these examples show that virtually all parts of the CNS can be used to varying degrees for processing the information associated with stress. Here we broadly consider which parts of the CNS are (1) concerned with processing the sensory information used to generate stress responses, (2) responsible for mediating the motor aspects of the stress response, and (3) involved with the integrative mechanisms that control stress responses in the face of influences from, for example, learning and memory mechanisms. To do this we explore concepts that are based on data derived from a number of experimental techniques, including lesions, neuroanatomical tract tracing, and the mapping of immediate early gene expression within the brain and spinal cord.

Many physiological stressors originating in the viscera are addressed by evoking simple reflexes to annul their potentially damaging consequences. Virtually no complex central processing is required and control is often exerted by classic negative feedback (homeostatic) mechanisms from the action of the target. An example of reactive homeostatic components of the stress response is the sympathetic activation evoked to counter the immediate visceral effects of many stressors. For example, if stress-related hypotension or hypoglycemia are prolonged or of sufficient intensity, they are rapidly negated by reactive stress responses that are evolutionarily rather old – sympathetically mediated vasoconstriction and catecholamine secretion by chromaffin cells, respectively (see **Comparative Anatomy and Physiology**).

In contrast, however, most stress responses typically have a more proactive (anticipatory) than a reactive (reflex) character, which involves complex neural processing. With stress activation of the hypothalamic-pituitary-adrenal (HPA) axis, for example, although adrenocorticotrophic hormone (ACTH) and corticosterone secretion are obviously triggered by the stressor, they are not motor responses that act to remove the immediate consequences of the stress in a manner similar to the reactive sympathetic responses just described. Instead, the actions of stress-induced

increases in circulating corticosterone levels (mediated in part by interactions with leptin, insulin, and the thyroid hormones) anticipate the possibility that the stressor will lead to a debilitating sequence of events, particularly the catabolic effects of negative energy balance, that require the mobilization of energy stores, particularly protein. Understanding the neural complexity required for processing what are effectively anticipatory events provides the framework for explaining why so many neural systems are involved with modulating stress responses.

Brain Regions Concerned with Processing Stress-Related Information

Sensory Processing

Generally speaking, virtually all extero- and viscerosensory modalities are processed along two types of pathway once they enter the CNS (Figure 1). The first, path A, is a relatively direct and rapidly effective route that requires little central integrative processing. These types of reflex pathways result in rapid and simply organized (stereotyped) motor

responses. Much of the neural processing for these reflexes occurs in the spinal cord (for the behavioral motor components of stress responses), hindbrain (for the autonomic motor aspects of stress responses), and hypothalamus (for the motor output of neuroendocrine stress responses). In path B, the second path, sensory information is also directed to those areas of the brain that provide the additional and often critical modulatory information about arousal state and behavioral planning (timing signals, priorities, etc.), so furnishing the animal with the adaptive plasticity for generating stress responses. Brain regions in the telencephalon (cerebral cortex, amygdala, hippocampus, and septal complex) provide pivotal contributions here, particularly with regard to the neural representations of sensory objects. Collectively, these processes can prioritize stress responses with relation to other behaviors (e.g., placing a higher priority on fleeing a predator than on feeding) and with modulating the organization of stress responses, decreasing or increasing their intensity based on past experience (learning and memory). As a consequence, they are also likely to be involved with generating the detrimental effects of chronic emotional stress. Finally,

Figure 1 A schematic representation of the two paths along which sensory information is processed in the brain. Path A is a reflex route that does not involve complex central processing and that allows for rapid stereotyped stress responses; path B is a route that allows sensory information to be integrated with other types of information within the brain and that provides stress responses with greater complexity, flexibility, and adaptability. Central neural connections are shown in black, with hormonal and feedback signals shown as dashed lines. The regions that constitute the central control networks in the brain are enclosed within the gray box in path B.

Figure 1 shows that the effects of a stress-associated motor event can serve as feedback signals to modulate the motor output of the system, both by reducing the level of sensory input and motor output (simple negative feedback) and by more indirect effects on central integrative processes.

Spinal cord Neurons in the dorsal horn of the spinal cord are the first recipients of nerve afferents from the skin and viscera that process information related to somatosensory modalities (pressure, temperature, and pain). The spinal cord also receives sensory information from muscle spindles related to body position. Dorsal horn neurons are involved with organizing reflexes related to stress responses, but they are not directly involved with generating the more complex motor events usually thought of as stress responses. However, dorsal horn neurons do project much of this sensory information to the hindbrain and thalamus for the higher-order processing (the sensory transduction and processing part of **Figure 1**, path B). Ultimately, higher-order processing can then influence the type of contextual information responsible for generating the stress responses that are accompanied by fear and anxiety. Clearly, because information related to pain can evoke ACTH release, nociceptive information entering the dorsal horn can affect neuroendocrine motor neurons in the hypothalamic paraventricular nucleus (PVH). However, the pathways responsible for this are not entirely clear.

Hindbrain Parts of the hindbrain receive first-order sensory information from the cranial nerves related to the visual (oculomotor) and vestibular systems, as well as somatosensory (the hypoglossal and trigeminal systems) and gustatory (the glossopharyngeal nerve) information from the oropharynx. In many respects how the hindbrain processes this information in a stress-related manner is similar to how exterosensory information is processed bidirectionally by the dorsal horn of the spinal cord (**Figure 1**) – information can initiate reflex loops and it can be passed further into the brain for more sophisticated processing. Projections from the parabrachial nucleus are probably important for projecting pain-related information received from the dorsal horn and cranial nerves that ultimately impact those parts of the hypothalamus regulating the adrenal gland.

The hindbrain is also critical for processing those sensory modalities originating in the internal environment that can generate stress responses. It receives numerous inputs from sensory receptors in the viscera that in general are conveyed to the nucleus of the solitary tract (NTS) by the vagus nerve and spinal

cord. In turn, the NTS initiates visceral reflexes such as the baroreceptor reflex that regulates cardiovascular function within a normal range. However, neural projections from the NTS along with other hindbrain regions also project this information to the forebrain (including regions in the hypothalamus such as the PVH) and telencephalon that in turn regulate the HPA axis directly. This explains why many viscerosensory stimuli (e.g., hypoglycemia and hypotension) can evoke robust ACTH and corticosterone secretion.

Thalamus With the exception of olfactory information (which enters the cortex directly and most likely impacts stress-related motor circuits by way of the amygdala and bed nuclei of the stria terminalis (BNST), all exterosensory modalities are processed by the thalamus before being projected to the amygdala and cerebral cortex. Consequently, those specific thalamic regions associated with particular sensory modalities have been implicated in processing stress-related sensory information. For example, the medial geniculate region is thought to contribute to the fear-conditioning evoked by pairing an auditory stimulus with foot shock.

Motor Regions

Spinal cord The spinal cord contains two sets of motor neurons that are directly related to expressing stress responses. First, alpha motor neurons in the ventral horn are the mediators of all behavioral motor system stress responses. And second, the intermediolateral column in the thoracic and upper lumbar spinal cord contains the sympathetic preganglionic neurons that innervate the adrenal medulla and are directly responsible for stimulating adrenaline release during stress. These cholinergic neurons also mediate other components of the sympathetic stress responses and are innervated by a variety of afferents including those from the hypothalamus.

Hindbrain Visceral stress responses are also mediated by sets of preganglionic neurons in the hindbrain. For example, stress-induced modifications to cardiovascular and other visceral functions are mediated through the dorsal motor nucleus of the vagus.

Hypothalamus The hypothalamus is a critical premotor region that can modulate most viscerally directed stress responses. It also contains all the motor neurons used for the neuroendocrine component of the stress response. Foremost among these are the

corticotropin releasing hormone (CRH) neurons in the medial parvocellular part of the PVH. The axons of these neurons terminate on the capillaries of hypophysial vasculature in the median eminence and release CRH and arginine vasopressin (AVP) to stimulate ACTH release from corticotropes in the anterior pituitary. The PVH and supraoptic nucleus also contain magnocellular neurons that release oxytocin and AVP during stress events. As with all other motor responses, these neuroendocrine neurons can be activated in relatively simple reflex manner (e.g., by hemodynamic stressors) as well as by inputs from telencephalic regions. In addition, the PVH provides strong projections to sympathetic and parasympathetic preganglionic neurons and is probably a key element in modulating the activity of these systems during stress.

One of the classic functions of the hypothalamus is the generation of motivated behaviors. These include ingestive, reproductive, and defensive behaviors. During the 1940s, Hess demonstrated that electrical stimulation of specific regions of the lateral hypothalamus

(LHA) elicit rage or fearful behavior. It is likely that the often inhibitory influences of stress on, for example, feeding and reproductive behaviors are integrated within the hypothalamus with the relevant control networks of these behaviors. The exact mechanisms used for these interactions are not clear, but again they very likely involve inputs from the telencephalon. Finally, it is important to remember that the hypothalamus contains the suprachiasmatic nucleus (SCH). In mammals, this cell group is the circadian clock, which can strongly influence the way stress responses are generated.

Afferents from those brain regions known to regulate the HPA axis and other stress motor functions are organized as two basic projection patterns (**Figure 2**): those that provide inputs directly to the PVH and those that provide indirect inputs, projecting first to other cell groups that in turn then project to the PVH. Neurons with direct inputs to the PVH can be divided into four afferent sets that provide the rich source of information for integration by neuroendocrine and pre-autonomic cell groups.

Figure 2 A schematic of the organization of inputs to the paraventricular nucleus of the hypothalamus. This nucleus is a key regulator of neuroendocrine and other autonomic stress responses. However, it receives only a restricted number of direct inputs from the telencephalon, hypothalamus, and hindbrain. Many other hypothalamic and telencephalic regions provide information indirectly by way of these more direct inputs. Finally, circadian timing signals from the suprachiasmatic nucleus impact the PVH directly and, to a greater extent, through other hypothalamic cell nuclei with direct inputs. ARH, arcuate nucleus; AVPV, anteroventral periventricular nucleus; CRH, corticotropin releasing hormone; DMH, dorsomedial nucleus; LHA, lateral hypothalamic area; NTS, nucleus of the solitary tract; OVLT, vascular organ of the lamina terminalis; PMv, ventral premammillary nucleus; PVH, paraventricular nucleus of the hypothalamus; SFO, subfornical organ; VMH, ventromedial nucleus of the hypothalamus.

1. The only direct telencephalic inputs to the PVH comes from some of the BNST and the substantia innominata (Figure 2, group A).

2. Two groups of direct PVH inputs originate intrahypothalamically (Figure 2, group B). First, the PVH is surrounded by local γ -aminobutyric acid (GABA)ergic neurons that are not organized as a distinct hypothalamic nucleus but that electrophysiological and anatomical data suggest form an important group of direct intrahypothalamic inputs (Figure 2, group B₁). They receive a major input from the SCH, from the infralimbic cortex, and from other hypothalamic nuclei such as the ventromedial and ventral premammillary nuclei, which in turn receive massive telencephalic inputs. Second, a well-defined group of projections (Figure 2, group B₂) originate in the arcuate and dorsomedial nuclei, in the preoptic area (in particular, the median preoptic and anteroventral periventricular nuclei), and the LHA. These nuclei also receive inputs from the telencephalon, including the BNST and lateral septal complex (LS). The overall function of these two groups of direct intrahypothalamic inputs is unclear. However, projections from the arcuate and perhaps the dorsomedial nucleus convey information about peripheral energy status derived from circulating leptin, insulin, and ghrelin, which are important for regulating the stress responses derived from changes to energy balance. Some neurons in this group may also constitute a set of neuroendocrine pattern generators similar in principle to those in the hindbrain and spinal cord that control patterning in the behavioral motor system.

The importance of input sets (1) and (2) to stress responses is that they relay information to the PVH from a host of diencephalic and telencephalic regions (Figure 2, groups A, B₁, and B₂). Thus, these areas each receive numerous topographically ordered inputs from the cortex, ventral subiculum (SUBv), amygdala, and LS. Collectively, these inputs are responsible for relaying a great deal of the information critical for controlling stress responses to exterosensory stimuli and under a variety of circumstances that requires complex telencephalic processing.

3. The SCH provides the circadian timing signal that regulates all behaviors and has a critical bearing on the expression of stress responses. Although the SCH provides a small direct PVH projection, its major output (Figure 2, group C) is to the subparaventricular zone in the peri-PVH region and the dorsomedial nucleus. Collectively, its efferents to these regions (Figure 2, group B₁, B₂, and C) are the likely mediators of circadian influence on the PVH-related stress responses.

4. Afferents from a variety of hindbrain nuclei project topographically within the PVH and convey viscerosensory information derived from the spinal cord, vagus, and glossopharyngeal nerves (Figure 2, group B₁). These inputs probably serve two functions; to stimulate patterns of ACTH secretion in response to homeostatic challenges that can generally be described as reflex in nature and to provide the gain control signals required for neuroendocrine CRH neuron function in the basal state. Afferents from the vascular organ of the lamina terminalis and the subfornical organ that provide humoral sensory information about blood osmolality and angiotensin II concentrations, respectively, can also, in terms of function, be included with these direct viscerosensory inputs.

Integrative Regions

Hindbrain The hindbrain contains monoaminergic cell groups that have very wide-ranging connections that in the past have been referred to as the reticular activating system. Included here are the locus ceruleus, the raphe nuclei, parts of the NTS, and pedunculopontine nuclei. Collectively, they receive sensory inputs from the oropharynx and viscera, as well as numerous inputs from the forebrain. They innervate virtually the whole of the neural axis and are thought to regulate behavioral arousal. In some instances (e.g., the locus ceruleus), they are implicated in the stress responses by virtue of their electrophysiological behavior and gene expression. Collectively, however, the precise role of these cell groups in regulating stress responses remains unclear.

Hippocampus It has been known for some time that hippocampal lesions or the severing of hippocampal efferents into the lateral septal complex disrupts ACTH secretion and, thus, glucocorticoid stress responses. The SUBv is the hippocampal subfield most clearly implicated in this context. SUBv lesions increase CRH and AVP gene expression in the neuroendocrine PVH and also elevate plasma ACTH concentrations, suggesting that the SUBv usually provides inhibitory inputs to the PVH. Although specific details about the pathways or the mechanisms involved are not understood, the absence of direct projections from any hippocampal region to the PVH demonstrates that these effects are not mediated directly. The best candidate in this regard is a SUBv-BNST-PVH pathway (Figure 2, group A). The most studied overall function of the hippocampus is in learning and memory, particularly regarding short-term spatial memory and animal navigation. However, how this

type of information relates to the modulation of stress responses is entirely unknown.

Septal complex The septal complex is a collection of forebrain cell groups that lie directly medial to the lateral ventricles. They are characterized by having bidirectional and topographically organized connections with the hippocampus; the LS receives afferents, and the medial septal complex projects back to the hippocampus. As such the LS is in a position to integrate information from all sensory modalities. By virtue of their efferent connections, the parts of the LS that are most closely associated with regulating endocrine stress responses are located in its rostral (LSr) and ventral (LSv) parts. Although the LSv provides sparse inputs directly into the PVH, it does project strongly to at least two regions that can affect stress responses directly: the peri-PVH region (Figure 2, group B₁) and those parts of the hypothalamic preoptic area that then project into the PVH (Figure 2, group B₂). In turn, LSv neurons receive topographically ordered projections from the SUBv. In addition to any effects it might have on the HPA axis, the LS probably plays an important role in the expression of defensive behavior and, as such, may well affect the ordering of behavioral priorities during stress events. Certainly, patterns of immediate early gene expression suggest that the LS is somehow concerned with modulating defensive behavior during fear conditioning.

Amygdala The amygdala has long been considered critical for regulating stress responses and their learned components that have fear as the emotional percept. However, the precise role of amygdala is still unclear with regard to its specific contribution. The amygdala is traditionally subdivided into the lateral, basolateral, medial, central, and cortical regions. However, recent debate has challenged the usefulness of the amygdala as a unitary concept, suggesting that a more viable division is first into cortical (with glutamate as a transmitter) and striatal (with GABA as a transmitter) parts, followed by four functional systems based on the segregation of inputs and outputs. In this scheme, the traditionally defined amygdalar nuclei are included into one of these functional systems. For example, the central nucleus of the amygdala is part of the striatal amygdala and, by virtue of its connections to the BNST and parabrachial nucleus, regulates the autonomic aspects of the stress response. Regarding outputs, the hippocampus and BNST are important components in the output structure of the amygdalar nuclei most closely associated with stress responses. Although again, like other parts of the telencephalon, the complex organization of

stress responses dictates that all parts of the amygdala are probably involved at some level.

Bed nuclei of the stria terminalis The BNST are a set of numerous, often small, and rather poorly differentiated cell groups located immediately rostral and dorsal to the preoptic area of the hypothalamus. Their precise role has proven difficult to define, mostly because experiments have targeted large regions that encompass a number of nuclei. However, neuroanatomical evidence suggests that each BNST cell group has precise and often distinct connections. As a whole, the BNST receive topographically organized projections from the amygdala and hippocampus and, in turn, project to many parts of the hypothalamus. The importance of the BNST to stress responses is that some of these nuclei receive projections from those parts of the cerebral cortex, amygdala and hippocampus (particularly the ventral hippocampal regions) associated with the overall regulation of the stress responses. Consequently, one of their major functions is to integrate and channel processed telencephalic information directly to the PVH and other parts of the hypothalamus (Figure 2, group A).

Cortex Because the cerebral cortex is ultimately involved with formulating and regulating all voluntary behaviors, it must be considered as a major integrative component of stress responses, particularly with respect to behavioral initiation, motor program selection, and prioritization. But as can be imagined, a detailed consideration of its function in this regard is beyond the scope of this article. Regarding cortical influences on neuroendocrine and autonomic motor output, these are generally indirect and are mediated through the LS, BNST, amygdala, and SUBv or through other hypothalamic nuclei that have direct neuroendocrine connections (e.g., Figure 2).

Glossary

<i>Amygdala</i>	Brain region involved in the central regulation of the stress response.
<i>Body mass index (BMI)</i>	The weight in kilograms divided by the square of height in meters.
<i>Cardiac myocyte</i>	A cell of myocardial origin.
<i>Dual-energy X-ray absorptiometry (DEXA)</i>	Imaging study assessing body composition and bone mineral density. A useful method for measuring body fat.
<i>Hypothalamic nuclei</i>	Neuron collections in the brain regulating a variety of hormonal secretions and functions.
<i>Prohormone</i>	The initial molecule (peptide in this case) from which the active hormone is derived.
<i>Renin-angiotensin-aldosterone system</i>	Endocrine system that regulates water homeostasis and blood pressure.

Brain natriuretic peptide (BNP) is a hormone of cardiac origin, secreted from the heart ventricles in response to pressure overload. It was isolated originally from porcine brain extracts, but it was soon discovered that heart was its main source. Natriuretic peptides (atrial natriuretic peptide, ANP; BNP; and C-type natriuretic peptide, CNP), deriving from three different genes, comprise a peptide family of high structural homology, as they share a 17-amino acid internal ring. Cardiac ANP and BNP act on the same peripheral receptors, causing diuresis, vasodilatation, and antagonism of the actions of renin and aldosterone. The source of CNP is kidney endothelium and its main action is the regulation of the vascular tone.

BNP is derived from a prohormone, an intracellular 108 amino acid precursor, which is cleaved into two fragments, a 76-amino-acid N-terminal fragment (NT-proBNP) and BNP. Both BNP and the NT-proBNP, have emerged as strong biological markers of cardiac dysfunction: levels of circulating BNP positively correlate with the severity of heart failure (HF) and BNP can improve cardiac disease diagnosis and management. Recombinant human BNP ("Natrecor", Scios Inc) has proved useful in the treatment of some forms of cardiac failure, especially in advance of cardiac surgery. BNP and NT-proBNP have the same diagnostic and prognostic value. Gender, body mass index (BMI) and age (through cardiac and renal function) may influence natriuretic peptide concentrations, but the underlying mechanisms for this are not well known.

Cardiac myocyte stretch, hormones (catecholamines, angiotensin II, and endothelin) and myocardial hypoxia are the main factors causing the observed

changes in the plasma concentrations of these peptides. Stretching of cardiac myocytes is followed by the activation of proBNP gene and *de novo* myocyte peptide synthesis and secretion and there is a positive correlation between the amount of stretch and the resulting increase in BNP and NT-proBNP concentrations. In the normal state, the atrium is the main cardiac production site, but as HF develops, there is a profound activation of ventricular BNP synthesis.

Brain Natriuretic Peptide and Stress Physiology

Besides their peripheral circulation and actions in water and blood pressure regulation, natriuretic peptides and their receptors (NPR-A, NPR-B, and NPR-C), are distributed throughout the central nervous system (CNS) of different species. In the CNS, they represent an important neuromodulatory system, which directly influences the secretion of stress hormones and behavioral manifestations such as arousal and anxiety.

In the CNS of the rat, BNP has a distribution that is different from that of ANP. Furthermore, high-affinity binding sites for BNP and ANP have been found in various brain regions of rats, such as area postrema and certain hypothalamic nuclei. In the CNS of humans and rodents NPR-A is located in the cortex and hippocampus, NPR-B in the amygdala and several brainstem sites, while NPR-C is found in many areas such as the neocortex, limbic cortex, hippocampus and amygdala.

In humans and rodents, ANP has an inhibitory effect on the hypothalamic-pituitary-adrenal (HPA) axis at the pituitary and hypothalamic levels, while CNP induces the opposite effect by stimulating the release of cortisol.

In rats, BNP administration into the cerebral ventricles did not modify the basal plasma corticosterone secretion (which is used as a measure of HPA activity). When rats were subjected to three different stressors (stress, electric shock, and restraint), BNP inhibited stress-induced elevation in plasma corticosterone in a dose-dependent manner. While there is evidence for the inhibitory role of BNP in the HPA axis, the effect of CNP is greater and more stress specific than that of BNP, perhaps due to the different distributions of NPRs in the CNS.

Brain Natriuretic Peptide and the Exercise-Stressed Myocardium in Healthy Individuals

BNP and NT-proBNP are elevated in healthy subjects after prolonged and strenuous exercise. Although these peptides have been established as strong biological

markers of heart disease, the underlying mechanisms that lead to exercise-induced elevation of BNP and NT-proBNP in healthy individuals are not well known.

Myocardial stress, expressed as increased ventricular pressure or cardiac output during exercise, may lead to increased synthesis of BNP and NT-proBNP concentrations in order to lower cardiac afterload by peripheral vasodilatation and diuresis. This relation between exercise and BNP levels seems to be time-dependent.

BNP is a well-known antagonist of the renin-angiotensin-aldosterone system. BNP is elevated in situations of increased central blood volume (fluid overload), such as edematous situations, HF, and exhaustive exercise. Ventricular wall stress is greatly increased in strenuous long-term exercise, as plasma volume increases by up to 22%. BNP is released into the circulation as a counterregulatory homeostatic response, and induces diuresis and vasodilatation and reduces pulmonary and systemic vascular resistance, resulting in reduction of left ventricular (LV) end-diastolic pressure. BNP increases immediately at the onset of, stays elevated during, and decreases with the termination of exercise. BNP is a good marker of volume regulatory response of the hemodynamically stressed myocardium.

Age and cardiac function influence BNP secretion. Thus, older and less trained individuals have higher levels of NT-proBNP. It should be noted that this elevation represents cardiac fatigue, which is different from that resulting from irreversible subclinical cardiac injury.

Brain Natriuretic Peptide and the Failing Heart

The value of cardiac peptides has been recognized by their inclusion in the recent European Guidelines for the diagnosis of chronic HF.

HF is characterized by progressive fatigue and dyspnea and leads to reduced tolerance to efforts. Increased wall stress and neurohormonal (adrenergic, renin-angiotensin-aldosterone, endothelin, and vasopressin) activation stimulate BNP and NT-proBNP secretion and these peptides negatively correlate to LV systolic function.

The majority of studies has proved the relationship between cardiac peptides and cardiac disease: BNP levels are higher in patients with LV hypertrophy and in patients with LV diastolic dysfunction and the specificity of BNP in detecting these situations has been well established. Additionally, BNP correlates with systolic blood pressure (SBP) and pulse pressure (PP) and PP increase has been recognized as an independent risk factor of cardiovascular disease.

BNP and NT-proBNP have become an important addition to the diagnostic tools of heart diseases. They were the first biomarkers to prove their value in screening for LV dysfunction, assessing the prognosis while monitoring patients, decision making during therapy, and predicting adverse cardiac events and readmissions in HF patients.

Brain Natriuretic Peptide and Myocardial Ischemia

BNP concentrations are elevated in individuals with stress-induced myocardial ischemia and the rise in BNP levels are related to the degree of ischemia induced. Additionally, baseline BNP levels before stress testing are higher in those who subsequently develop stress-induced ischemia.

The combination of exercise electrocardiography (ECG) with baseline or peak BNP concentrations increases diagnostic accuracy compared with ECG only. The exact mechanism underlying the association between myocardial ischemia and the release of BNP are not well known. It is possible that the ischemia-induced decrease in LV function and/or ischemia-induced neurohormonal activation may increase ventricular wall stress and BNP secretion.

NT-Pro BNP in Relation to Metabolic Risk Factors

BNP and NT-proBNP levels correlate negatively with BMI and increased expression of clearance receptors by adipose tissue was initially hypothesized to be responsible for the rapid degradation of BNP in obese individuals. In a recent study using dual-energy X-ray absorptiometry (DEXA) instead of BMI as a measure of obesity, lean body mass and not fat mass was responsible for the association between higher BMI and lower BNP and NT-proBNP levels. A substance produced by lean mass that suppresses BNP synthesis or release was then hypothesized to be the underlying cause of this association.

Furthermore, an inverse association between serum NT-proBNP and other risk factors, such as fasting serum insulin, cholesterol and triglycerides and metabolic syndrome itself, has been found independently of age and gender in the adult population. Indeed, NT-proBNP concentrations correlate with PP and the response curve is shifted to the right in adults with the metabolic syndrome.

Brain Natriuretic Peptide and NT-ProBNP in Pediatrics

Reference values of NT-proBNP serum concentrations in umbilical cord and in healthy neonates and

children show a significant increase in the first days of life followed by a rapid decrease during the first year and a gradual decrease throughout infancy. This change may reflect an adaptive mechanism to extra-uterine physiology.

Similarly to adults, NT-proBNP and BNP concentrations are elevated in children with LV dysfunction. Children with congenital or acquired heart diseases, such as dilated cardiomyopathy and myocarditis have elevated NT-proBNP levels, depending on the type and the severity of the disease. Furthermore, NT-proBNP levels are higher in children with HF and are negatively correlated with ejection fraction and positively correlated with New York Heart Association clinical score. There is also a correlation between BNP levels and left-to-right shunt, ventricular volume, and pulmonary-to-systemic pressure ratio in high-pressure lesions.

In conclusion, despite its name brain natriuretic peptide seems to be the least of the three natriuretic peptides involved in CNS regulation of stress. In contrast, it is an established biological marker, extremely useful in the diagnosis and management of acute cardiac incidents as well as the evaluation of exercise-induced myocardial stress in healthy individuals and cardiac patients.

Glossary

Amnesia
Cognitive functions

Metabolism

Loss or impairment of memory.

Mental processes related to thinking, such as memory, orientation, attention, concentration, and perception.

The sum of the chemical processes in the body by which complex substances are

	made and broken down to maintain tissue and organ function.
<i>Posttraumatic amnesia (PTA)</i>	Amnesia relating to events that occurred after the trauma that caused it.
<i>Retrograde amnesia (RA)</i>	Amnesia relating to events that occurred before the trauma that caused it.

Nature and Context of Brain Trauma

In Western countries in peacetime, 1 in 50 of the population will seek medical attention because of head injury each year and about 1 in 5 of these will be admitted to the hospital. Young men ages 15–25 years are particularly liable to suffer such trauma, with the elderly as the next most common group. The human brain lies well protected inside the thick bone of the skull, and it usually takes an external blow of considerable impact to transmit destructive forces to the underlying brain. The most common cause of such injuries is falls, followed by road traffic accidents, assaults, and, less commonly, work-related and sports injuries.

As many as half of those admitted to hospital after brain trauma will have consumed alcohol shortly beforehand. This may cloud the individual's awareness of the otherwise alarming circumstances of the injury. Thus, the young man who is intoxicated may not recall falling from a balcony or being struck by a passing car when the effects of the alcohol wear off. In addition, however, by its very nature brain trauma tends to result in a period of confusion associated with lack of memory, or amnesia. The period of lost memory is divided into that which preceded the trauma, retrograde amnesia (RA), and that which followed it, posttraumatic amnesia (PTA). After injury, the person may not be able to recall events that occurred minutes, hours, days, or months before impact. There is a tendency for the duration of this period of RA to shrink with the passage of time but, in most cases of severe brain trauma, the circumstances immediately preceding the injury are never remembered. PTA is defined as the period of loss of memory between injury and the time the person's confusion resolves and he or she regains continuous memory of day-to-day events. Indeed one of the most useful ways of classifying the severity of brain damage is to measure the duration of PTA. Head injuries are classified as mild, moderate, or severe according to whether the PTA is less than an hour, less than a day, or more than a day, respectively. In some people, the PTA can extend for months.

It might be regarded as a blessing that some victims of serious road accidents, vicious assaults, or terrifying falls have no memory of the event or its

early aftermath and so are spared painful and stressful recollections. Thus, the process of the ambulance journey, emergency room admission, surgery, and intensive care management may all be forgotten. In contrast, if any or all of these events are experienced and remembered they may be perceived as stressful.

Even in a state of altered awareness or reduced consciousness after brain trauma, the individual may be agitated and, to all intents and purposes, anxious and stressed. It is not uncommon to see restless behavior with all the physical accompaniments of a stress reaction during the early postinjury period. Thus, it is incorrect to assume that the absence of memory of stress in the longer term means that stress has not been experienced.

Nontraumatic Brain Injuries

Trauma is not the only form of sudden insult to the brain. Similar acute damage can occur from a number of other causes such as stroke, lack of oxygen, and infection.

- **Stroke:** The term stroke essentially implies an interruption of the blood supply to part of the brain. This may be because of a blockage of the blood flow, resulting in an ischemic stroke, or leakage of blood (i.e., hemorrhage), described as a hemorrhagic stroke. Both come on quickly and usually without warning.

- **Anoxic and metabolic damage:** A number of circumstances can result in the brain being denied oxygen and/or glucose, both of which are essential to normal function, or metabolism. The brain is probably the most sensitive organ in the body in terms of its need for oxygen and glucose. Lack of oxygen is referred to as hypoxia (or anoxia) and may result from cardiac or respiratory arrest, choking, strangulation, drowning, carbon monoxide poisoning, or drug overdose. The commonest cause of lack of glucose (hypoglycemia) is insulin overdose in people with diabetes. Metabolic disturbances other than lack of glucose include sudden disruption to the body chemistry in association with serious disorders of the liver or kidneys. Finally, toxic chemicals may act by interfering with oxygen or glucose supply or poison the brain by another mechanism. For convenience, these uncommon cases are often grouped with hypoxic metabolic damage.

- **Infection:** Infection of the brain (encephalitis or brain abscess) or its surrounding tissues (meningitis) may cause serious disruption to the functioning of the brain. Although this may be short-lived and temporary, some individuals are left with significant residual problems and are regarded as having sustained

permanent brain damage. People whose body defenses are impaired (e.g., those with AIDS or those being treated with immunosuppressant drugs) are particularly liable to these conditions.

Each of these forms of brain injury have characteristics peculiar to them, but, as in the case of trauma, all tend to occur suddenly. Thus, the individuals affected will usually have been functioning normally, going about their everyday lives when they are struck down with a serious event. The subsequent stressful events of hospital admission, intensive care, and monitoring are also similar to trauma cases. In contrast to trauma, these people may recall the onset of symptoms and remember more details of their early treatment.

Clearly in cases of drug overdose, self-hanging, or drowning resulting in hypoxic brain injury, stress may have been a major factor preceding the brain injury and may persist afterward. Although the link is not firmly established, stress may contribute to high blood pressure (hypertension), which is a major risk factor for both ischemic and hemorrhagic stroke.

Consequences of Brain Injury

Irrespective of the exact cause, injury to the brain results in loss of nerve cells, disturbance of connecting pathways within the nervous system, and chemical, including hormonal, changes. Because the brain is essentially the organ that controls all that we think, feel, and do, when it is damaged the effects can be complex. Brain injury may result in impairments of movement (motor function); of sensation (sensory function); of vision, hearing and balance, smell, and taste (special senses); and of heart beat, respiration, and control of bowel and bladder (autonomic function). In addition, how injured people perceive the world and their abilities to remember, concentrate, reason, and judge (cognitive functions) may also be impaired. The injured individual's emotional state may be disturbed, and the attributes that constitute their individual personality, and so how others see them, are also frequently altered.

Often, especially in severe cases, those who survive brain injury present with a complex mixture of physical, cognitive, emotional, and behavioral disorders. Disentangling features of an individual's behavior that may relate to stress from those resulting directly from the damage itself is often difficult or impossible.

People commonly report the phenomenon of frustration after brain damage. There is frustration at the loss or impairment of physical skills but also at cognitive difficulties such as not being able to remember things, find the correct word, or sustain

concentration on a task. The process of rehabilitation involves relearning simple skills, which may assume the form of daunting tasks that the individual may feel incapable of achieving. The physical and psychological impairments limit the activities the person can do successfully, from basic aspects of self-care and domestic chores to managing his or her own finances. The successful and resourceful husband and father may become a dependent member of the family, unable to fulfill these roles. Even those who recover to a greater degree may find both work and leisure pursuits restricted. Loss of employment after brain trauma is common, which in turn may result in financial hardship. Thus, the person may be unable to afford to pay the mortgage or rent, to keep a car, to take a holiday, or to go to a football game. These events and the change of personality that may occur after injury contribute to the high frequency of marital disharmony and breakdown that is well recognized after brain trauma.

It is apparent, therefore, that the individual who survives significant brain injury may experience a number of consequences that are recognized as being major sources of stress in the general population. Unemployment, change or loss of home, divorce, loss of friends, and inability to do normal leisure activities are all common. Added to these may be feelings of guilt, low self-esteem due to disfigurement or disability, and unfavorable reactions from strangers. Those who suffer more minor injuries and lesser degrees of loss may still experience considerable stress at their inability to fulfill tasks previously performed easily.

An additional major source of anxiety and stress in some cases of brain trauma is the legal procedures related to claiming compensation. In general, the process is protracted, involving repeated examinations because of the adversarial nature of most Western legal systems.

Posttraumatic Stress Disorder

Posttraumatic stress disorder (PTSD) is a specific psychiatric diagnosis whose essential feature is the development of characteristic symptoms following an extremely traumatic experience associated with threatened death or serious injury. The individual re-experiences the event in various ways, avoids stimuli associated with the trauma, and shows increased arousal. The symptoms persist for at least a month and are associated with a significant disruption of the individual's lifestyle.

Currently there is a degree of consensus that PTSD is uncommon after brain trauma, but controversy continues as to its actual frequency. Some authorities have

suggested that, because brain injury results in loss of the memory of the injury, PTSD cannot co-exist. Others suggest that it may be more common after milder injuries to the brain, when the loss of memory, both RA and PTA, is shorter. Thus, the individual may recall the circumstances leading to the injury or the stress of emergency treatment, and posttraumatic stressful circumstances are recalled. Finally, it has been suggested that even if the person has no direct memory of the event he or she may develop PTSD as a reaction to the medical sequelae of the injury.

There have been a few reports of PTSD occurring after stroke and other forms of nontraumatic brain injury. Certainly people who recall periods in intensive care units, for whatever cause, may view the experience as life threatening and suffer from disturbing recollections of the circumstances associated with increased arousal. Whether such people strictly fulfill the criteria for PTSD is probably not as important as recognizing the severe stress syndromes that do occur.

Stress in Families

No account of stress associated with traumatic and nontraumatic brain injury would be complete without at least a mention of the effect that an individual's brain injury has on other family members. Individuals who have suffered severe brain damage, in addition to not recalling the event and the early period in hospital, may have little insight into how they have been altered by the experience. Their families, however, will often have spent agonizing days or weeks wondering if their loved ones would survive, followed by anxious weeks or months wondering how much recovery would occur. With the passage of time, they may then face the adjustments to their lives resulting from what is essentially the loss of a spouse, partner, parent, or supportive son or daughter. Contending with changes in roles within a family, coping with behavioral and personality changes, and dealing with the loss of the principal wage earner can impose huge burdens on other family members.

There is increased recognition of, although still inadequate provision for, the effects of stress on carers in these circumstances. Ill health, both physical and mental, is common in the family members of those who survive severe brain injury. Clearly the same major events – loss of income, change of accommodation, loss of friends, and restriction of social life – can affect all family members. Divorce is common. The spouse or partner may have to give up his or her own job or career to become a caregiver or, alternatively, may have to seek employment to maintain an income. Children may also find themselves having to assume the responsibility of caring for a brain-injured parent, disrupting their education or career plans. The spouse, in having to give attention to the injured husband, or parents, in focusing on an injured child, may be unable to provide support to other children in the family, whose mental health and scholastic performance may suffer.

As with other sources of stress, families vary in their ability to cope. There is no direct correlation between the severity of the injury and its consequences and the level of stress experienced. Brain damage that is apparently minor may result in changes in an individual's personality or behavior that other members of the family may find difficult to deal with. There is fortunately a growing awareness of this phenomenon, with professional help available to assist families.

Stress-Reducing Interventions for Women with
Breast Cancer

Glossary

<i>BRCA1, BRCA2</i>	Two genes that, when damaged or mutated, greatly increase the risk of developing breast and/or ovarian cancer; those with a mutation have a 50% chance of passing it on to their children.
<i>Breast-conserving surgery</i>	The removal of a breast tumor and a small margin of normal tissue (also called lumpectomy); radiation therapy is often used in conjunction with breast-conserving surgery.
<i>Breast self-exam</i>	Examining one's breast area visually and by touch for suspicious changes such as lumps or swelling, skin irritation or dimpling, or nipple pain or retraction; most breast cancers are identified by women themselves.
<i>Mammogram</i>	An x-ray of the breast that can identify abnormalities before they can be felt by a woman or her health-care practitioner and before other physical symptoms develop.
<i>Metastasis</i>	The spread of cancer from the site of origin to other regions of the body via the lymph system or the bloodstream.
<i>Recurrence</i>	Cancer that has returned after treatment; breast cancer can recur locally (at the same site), regionally (in the nearby lymph nodes), and distantly (e.g., in the lungs or bone).

Breast cancer is a malignant tumor that develops from the cells of the breast. It is the most common cancer, aside from skin cancer, among women. Although the incidence of breast cancer has been steadily increasing among American women, this rate of

increase began to slow in the 1990s, and mortality rates are now declining. Breast cancer can also occur in men but much more rarely. The likelihood of long-term survival, in part, depends on the extent of spread of the disease. If cancer is localized to the breast, the estimated 5-year survival rate, based on women who were diagnosed in prior years, is 97%; if it has spread to surrounding regions, the rate is 77%; and if it has metastasized to distant sites, the rate is 22%. Due to developments in medical care, the survival estimates for women diagnosed today are presumed to be better.

Stresses Associated with Breast Cancer Risk

All women are at risk for breast cancer. However, particular factors such as a family history of the disease, early menarche or late menopause, and not bearing children or having children after the age of 30 increase the likelihood of developing it. Although more is being discovered about potential predictors, much uncertainty remains. Established risk factors can explain only a small amount of the occurrence of breast cancer, and many women diagnosed with the disease have none of these risk factors. Women concerned about their risk for breast cancer have limited preventive options because factors such as one's family history cannot be altered and recommended modifications in diet, exercise, alcohol consumption, and body weight are no guarantee against contracting the disease.

Not surprisingly, women at higher risk for breast cancer tend to be more distressed. Women with a family history of the disease often overestimate their risk and their concern may be fairly resistant to cancer-risk counseling. Anxiety about their own likelihood of developing breast cancer can be compounded by worry about the health of other affected and unaffected family members.

An important issue is how concern about cancer or being at increased risk affects health behaviors, especially those related to early detection and treatment. Screening procedures such as clinical and breast self-examinations and mammograms can provoke anxiety. Screening mammography has a significant false-positive rate, meaning that many women are subjected to unnecessary worry and the discomfort of diagnostic biopsies. Despite this, having a family history of breast cancer, being at higher risk, having a history of breast problems, and worrying more about breast cancer are associated with a greater

rather than a lower likelihood of seeking a mammogram. However, it has also been documented that anxiety can contribute to delay in seeking medical care once a woman discovers a suspicious breast lump.

A small proportion of breast cancer cases, approximately 5–10%, can be attributed to an inherited susceptibility that greatly increases one's likelihood of getting the disease. A blood test to detect relevant inherited mutations in the genes *BRCA1* and *BRCA2* is now available. However, the stresses associated with obtaining this risk information are complex. In order for results to be interpretable, the testing process often requires extensive documentation of the cancer history in one's family. This can be onerous if there are rifts or a lack of contact among family members. In addition, to identify the particular mutation potentially at work in a family, an affected family member is ideally the first individual tested. This is something that unaffected family members may be reluctant to ask them to do.

Genetic information is especially potent because knowledge about one individual's status will reveal risk information about family members. Relatives may or may not be interested in learning their own risk. Genetic information can also be more complex than most health-related information. In the case of hereditary breast cancer, carrying an identified mutation means that one has only an increased probability of developing the disease. If one is found to carry a mutation, courses of action include more vigilant surveillance, taking the anti-estrogen drug tamoxifen, or prophylactic surgical removal of healthy breasts. Prophylactic surgery is a fairly radical option that is thought to significantly reduce the likelihood of getting breast cancer, but will not eliminate the possibility that it will develop. Thus, decisions about one's options once one has this knowledge can also be a source of turmoil. Although women who test positive and opt for prophylactic surgery have higher distress immediately following the receipt of their test results than those who opt for surveillance or test negative, in the long term, their levels of distress decline, probably due to a reduction in fear of developing cancer. Finally, concerns about employment or insurance discrimination based on the results of genetic tests remain legitimate worries.

Despite these challenges, for some women the advantages of having risk information outweigh the disadvantages, and it can assist them in making decisions about their health care. Early surveys of women at risk for cancer generated concern that those who were more psychologically distressed would be more likely to seek genetic testing. However, research with women actually offered test results have shown that those who opt to learn their status

have more cancer-specific distress but no more global distress than those who opt not to. Learning test results appears to result in decreased distress, especially for noncarriers, but more negative psychological outcomes can occur if test results conflict with one's prior expectations. Long-term follow-up studies of mutation carriers indicate that levels of distress 5 years after learning that one carries a mutation are predicted by factors that existed at pretest such as: worry about cancer, communication difficulties with family members, having young children, having lost a family member to cancer, and greater perception of risk.

Concern about developing breast cancer presents quandaries for women with respect to other health-related decisions. For instance, postmenopausal estrogen replacement therapy can relieve distressing menopausal symptoms and prevent postmenopausal osteoporosis, both important threats to women's health, but it also increases the risk for breast cancer and is no longer considered useful in preventing heart disease. Women are encouraged, with the help of their health-care provider, to determine their own preferred course of action. Women making such decisions about their health care, in general, have been assisted by increased reporting of health-related issues in the media. However, when new reports contradict prior ones, this can be confusing and worrisome.

Stresses Associated with Breast Cancer Diagnosis and Treatment

Breast cancer involves a myriad of stressors. Diagnosis, treatment, recovery, and long-term survival present a series of challenges that can contribute to psychological morbidity. In fact, a small proportion of women who have been treated for breast cancer show symptoms consistent with posttraumatic stress disorder. An initial diagnosis of breast cancer can provoke worries about loss of physical functioning, social value, and financial resources and fears of death. The time between diagnosis and treatment is an extremely stressful period, exacerbated by trying to gather and understand new information.

Treatment for breast cancer usually involves surgical removal of part or all of the breast. Pain, numbness, and arm stiffness and swelling are common. The cultural connection of the breast to women's femininity and sexuality means that surgery for breast cancer can threaten a woman's sense of attractiveness and alter sexual relations. Adjuvant treatment such as radiation therapy, chemotherapy, and hormonal therapy represent considerable physical and psychosocial challenges. Side effects from radiation can include itching, swelling, skin changes, and especially fatigue.

With chemotherapy, there is nausea, hair loss, weight changes, infections, mouth sores, and altered taste sensations. Such physical effects can lead to depression, low self-esteem, family disruptions, sexual difficulties, and fear of losing a partner. Ironically, even the end of treatment can be difficult for patients because the attention from medical personnel is lost and the support of family and friends may diminish. The long-term challenges of living with breast cancer include worry about recurrence and fears about cancer striking family members.

Coping with breast cancer can be especially difficult for certain populations of women. Single women, for instance, can suffer from isolation, inadequate support, and fears about disclosing their disease to new partners. Women may be especially vulnerable to suffering economically when struck with a life-threatening illness. Low-income women who develop breast cancer, or women whose financial situation deteriorates due to their illness, have numerous practical difficulties that compound an already difficult experience.

Of course, breast cancer not only affects the individual dealing with the disease but impacts those in her social network as well. Partners of breast cancer patients often show significant psychological distress as they deal with the demands of added duties and responsibilities in addition to worry about their partner's health. Coping with a life-threatening illness also has numerous ramifications for the family. Breast cancer can disrupt the social, financial, vocational, and educational goals of family members. A key stressor faced by families is dealing with the uncertainty that the illness can bring.

Fortunately, more attention has been devoted to issues of quality of life for women with breast cancer in recent decades. Some of the stressors associated with breast cancer diagnosis and treatment have been alleviated by developments in medical practice and changes in social mores. These include the use of less disfiguring procedures such as breast-conserving surgery, more openness about the once taboo topic of cancer, the availability of more information about the treatment and experience of breast cancer, the opportunity to play a more active role in one's medical treatment, and increased availability of supportive resources. However, some of these developments can also be stressful. For instance, being involved in decisions about treatment can involve assimilating a considerable amount of new information during a stressful period and perhaps feeling more responsibility for the treatment outcome. Fortunately, decision aids to assist physicians in clearly conveying various breast cancer treatment options and eliciting patients' preferences have shown promise in

increasing knowledge and decreasing patients' feelings of conflict about decision-making. Interactive CD-ROMs and audiotapes that patients can use themselves have also been developed.

The Role of Stress in the Onset and Progression of Cancer

The notion that stress might play a role in the occurrence of cancer is not new. The suggestion that stress and grief could predispose women to breast cancer was ventured in the scientific literature in the late 1800s. This idea is also embraced by women in the general public; when queried about the possible causes of breast cancer, stress is a prominently mentioned factor. Some research has focused on the effect of stressful life events, in particular, on the onset of breast cancer. Methodological difficulties in this area, however, include relying on retrospective accounts of stressful life events in women already diagnosed with cancer or a breast abnormality, who may have recall biases due to knowledge of their diagnosis. Some investigators have sought to remedy this problem by making assessments of stress after women have had a diagnostic biopsy for a breast abnormality but before they have learned their results. More methodologically rigorous prospective studies would necessitate following a large number of individuals over an extended period of time to assess the relationship between the occurrence of stressful life events and the subsequent onset of breast cancer. Other methodological problems of studies in this area include lack of comparability of cases and controls on meaningful variables such as age, and the fact that the period during which the occurrence of stressful events is assessed is typically shorter than the several years in which tumors are suspected to develop. A recent meta-analysis by Petticrew examined the most rigorous investigations in this area and concluded that there was no significant relationship between adverse life events such as bereavement and the onset of breast cancer.

Can stress or the reduction of stress play a role in the course of cancer once it is diagnosed? The results of one intervention study have generated much interest and enthusiasm. Women with metastatic breast cancer were assigned either to a supportive group where they were encouraged to express their emotions about cancer and confront their feelings about the disease, which could help alleviate their stress, or to a control group. Although the investigators were only anticipating enhancing quality of life, the group that received the intervention survived an average of almost 18 months longer than the control group. Recent studies of psychosocial interventions,

however, have failed to replicate this survival effect, although beneficial psychosocial outcomes were consistently demonstrated.

One way in which stress might influence the progression of cancer is through alterations in immune functioning. Such changes can result directly from the action of the central nervous system or of stress-elicited hormones, or through changes in behavior such as eating, sleeping, smoking, or adhering to medical care. Women with breast cancer reporting higher levels of stress have shown lowered cellular immune responses, including natural killer cell toxicity and T-cell responses. Cognitive-behavioral stress management intervention, in turn, can improve cellular immune function in breast cancer patients. It is important to determine if such changes could influence tumor growth and metastasis in clinically meaningful ways. For instance, a disrupted diurnal rhythm of the stress hormone cortisol has been associated with a shorter length of survival, mediated through suppressed natural killer cell activity.

Stress-Reducing Interventions for Women with Breast Cancer

Regardless of whether stress reduction strategies will increase the length of survival of women with breast cancer, interventions that help women deal with the challenges of the disease can improve quality of life. A number of supportive interventions for cancer now exist. These include cognitive-behavioral interventions that focus on changing specific thoughts or behaviors or on learning specific coping skills, educational programs that provide information, psychotherapy and counseling by professionals, and support provided by nonprofessionals such as groups of fellow patients. In addition, relaxation and attentional distraction have been used to deal with the nausea and vomiting associated with chemotherapy. Such interventions have proved to be beneficial. A meta-analysis by Meyer and Mark of randomized, controlled-outcome studies concluded that psychosocial interventions for cancer (which have included primarily breast cancer patients) have positive effects on emotional adjustment, functional adjustment, and treatment- and disease-related symptoms. Recently developed interventions have included components such as mindfulness, physical exercise, and written emotional disclosure.

With limited resources for supportive interventions, and the fact that not all cancer patients wish or are able to make use of them, it is important to consider viable alternatives to counseling and support groups. This has brought a focus on means to enhance natural support from those already in an individual's social network and alternatives to face-to-face interactions such as computer-facilitated support systems. The proliferation of self-help books and information available on the Internet related to breast cancer also offer promise.

Definition and Assessment

A Mediation Model of Burnout and Engagement

Implications for Interventions

Glossary

<i>Burnout</i>	A psychological syndrome of exhaustion, cynicism, and inefficacy, which is experienced in response to chronic job stressors.
<i>Cynicism</i>	A negative, callous, or excessively detached response to various aspects of the job.
<i>Engagement with work</i>	The positive antithesis of burnout, which is characterized by energy, involvement, and efficacy.
<i>Exhaustion</i>	Feelings of being overextended and depleted of one's emotional and physical resources.
<i>Inefficacy</i>	Feelings of incompetence and lack of achievement in work.

Definition and Assessment

Burnout is a psychological syndrome of exhaustion, cynicism, and inefficacy in the workplace. It is considered to be an individual stress experience embedded in a context of complex social relationships, and it involves the person's conception of both self and others on the job. Unlike unidimensional models of stress, this multidimensional model conceptualizes burnout in terms of its three core components.

Burnout Components

Exhaustion refers to feelings of being overextended and depleted of one's emotional and physical resources. Workers feel drained and used up, without any source of replenishment. They lack enough energy to face another day or another person in need. The exhaustion component represents the basic individual stress dimension of burnout.

Cynicism refers to a negative, hostile, or excessively detached response to the job, which often includes a loss of idealism. It usually develops in response to the overload of emotional exhaustion and is self-protective at first – an emotional buffer of detached concern. But the risk is that the detachment can turn into dehumanization. The cynicism component represents the interpersonal dimension of burnout.

Inefficacy refers to a decline in feelings of competence and productivity at work. People experience a growing sense of inadequacy about their ability to do the job well, and this may result in a self-imposed verdict of failure. The inefficacy component represents the self-evaluation dimension of burnout.

What has been distinctive about burnout is the interpersonal framework of the phenomenon. The centrality of relationships at work – whether it be relationships with clients, colleagues, or supervisors – has always been at the heart of descriptions of burnout. These relationships are the source of both emotional strains and rewards, they can be a resource for coping with job stress, and they often bear the brunt of the negative effects of burnout. Thus, if one were to look at burnout out of context and simply focus on the individual exhaustion component, one would lose sight of the phenomenon entirely.

The principal measure of burnout is the Maslach Burnout Inventory (MBI), which provides distinct assessments of each of the three burnout components. Different forms of the MBI have been developed for different types of occupations: the human services survey (MBI-HSS), the educators survey (MBI-ES), and the general survey (MBI-GS). As a result of international interest in burnout research, the MBI has been translated into many languages.

Burnout Correlates

Unlike acute stress reactions, which develop in response to specific critical incidents, burnout is a cumulative stress reaction to ongoing occupational stressors. With burnout, the emphasis has been more on the process of psychological erosion and the psychological and social outcomes of this chronic exposure, rather than just the physical ones. Because burnout is a prolonged response to chronic interpersonal stressors on the job, it tends to be fairly stable over time.

Health Symptoms Of the three burnout components, exhaustion is the closest to an orthodox stress variable, and therefore is more predictive of

stress-related health outcomes than the other two components. Exhaustion is typically correlated with such stress symptoms as headaches, chronic fatigue, gastrointestinal disorders, muscle tension, hypertension, cold/flu episodes, and sleep disturbances. These physiological correlates mirror those found with other indices of prolonged stress. Similarly parallel findings have been found for the link between burnout and various forms of substance abuse.

In terms of mental, as opposed to physical, health, the link with burnout is more complex. It has been assumed that burnout may result in subsequent mental disabilities, and there is some evidence to link burnout with greater anxiety, irritability, and depression. However, an alternative argument is that burnout is itself a form of mental illness, rather than a cause of it. Much of this discussion has focused on depression, and whether or not burnout is a different phenomenon. Research has demonstrated that the two constructs are indeed distinct: burnout is job-related and situation-specific, as opposed to depression, which is general and context-free.

Job Behaviors Burnout has been associated with various forms of job withdrawal – absenteeism, intention to leave the job, and actual turnover. However, for people who stay on the job, burnout leads to lower productivity and effectiveness at work. To the extent that burnout diminishes opportunities for satisfying experiences at work, it is associated with decreased job satisfaction and a reduced commitment to the job or the organization.

People who are experiencing burnout can have a negative impact on their colleagues, both by causing greater personal conflict and by disrupting job tasks. Thus, burnout can be contagious and perpetuate itself through informal interactions on the job. There is also some evidence that burnout has a negative spillover effect on people's home life.

Engagement: The Opposite of Burnout

The opposite of burnout is not a neutral state, but a definite state of mental health within the occupational domain. Engagement with work is a productive and fulfilling state, and is defined in terms of the same three dimensions as burnout, but the positive end of those dimensions rather than the negative. Thus, engagement consists of a state of high energy (rather than exhaustion), strong involvement (rather than cynicism), and a sense of efficacy (rather than inefficacy).

One important implication of the burnout–engagement continuum is that strategies to promote engagement may be just as important for burnout

prevention as strategies to reduce the risk of burnout. A workplace that is designed to support the positive development of the three core qualities of energy, involvement, and effectiveness should be successful in promoting the well-being and productivity of its employees, and thus the health of the entire organization. From this perspective, health is not limited to the physical or emotional well-being of individuals but is evident in enduring patterns of social interactions among people.

A Mediation Model of Burnout and Engagement

Inherent to the fundamental concept of stress is the problematic relationship between the individual and the situation. Thus, prior research has tried to identify both the key personal and job characteristics that put individuals at risk for burnout. In general, far more evidence has been found for the impact of job variables than for personal ones. These job factors fall into six key domains within the workplace: workload, control, reward, community, fairness, and values.

However, more recent theorizing has argued that personal and job characteristics need to be considered jointly within the context of the organizational environment. The degree of fit, or match, between the person and the job within the six areas of work life, will determine the extent to which the person experiences engagement or burnout, which in turn will determine various outcomes, such as personal health, work behaviors, and organizational measures. In other words, the burnout–engagement continuum (with its three dimensions) mediates the impact of the six areas of work life on important personal and organizational outcomes (see [Figure 1](#)).

Job Characteristics: Six Areas of Work Life

An analysis of the research literature on organizational risk factors for burnout has led to the identification of six major domains. Both workload and control are reflected in the demand–control model of job stress, and reward refers to the power of reinforcements to shape behavior. Community captures all of the work on social support and interpersonal conflict, while fairness emerges from the literature on equity and social justice. Finally, the area of values picks up the cognitive-emotional power of job goals and expectations.

Workload Both qualitative and quantitative work overload contribute to burnout by depleting the capacity of people to meet the demands of the job.

Figure 1 The role of burnout in mediating the impact of work life on personal and organizational outcomes.

When this kind of overload is a chronic job condition, there is little opportunity to rest, recover, and restore balance. A sustainable workload, in contrast, provides opportunities to use and refine existing skills as well as to become effective in new areas of activity.

Control Research has identified a clear link between a lack of control and high levels of stress and burnout. However, when employees have the perceived capacity to influence decisions that affect their work, to exercise professional autonomy, and to gain access to the resources necessary to do an effective job, they are more likely to experience job engagement.

Reward Insufficient recognition and reward (whether financial, institutional, or social) increases people's vulnerability to burnout, because it devalues both the work and the workers, and is closely associated with feelings of inefficacy. In contrast, consistency in the reward dimension between the person and the job means that there are both material rewards and opportunities for intrinsic satisfaction.

Community Community has to do with the ongoing relationships that employees have with other people on the job. When these relationships are characterized by a lack of support and trust and by unresolved conflict, then there is a greater risk of burnout. However, when these job-related relationships are working well, there is a great deal of social support, employees have effective means of working out disagreements, and they are more likely to experience job engagement.

Fairness Fairness is the extent to which decisions at work are perceived as being fair and equitable. People use the quality of the procedures and their own treatment during the decision-making process as an index of their place in the community. Cynicism, anger, and hostility are likely to arise when people feel they are not being treated with the respect that comes from being treated fairly.

Values Values are the ideals and motivations that originally attracted people to their job, and thus they are the motivating connection between the worker and the workplace, which goes beyond the utilitarian exchange of time for money or advancement. When there is a values conflict on the job and thus a gap between individual and organizational values, employees will find themselves making a trade-off between work they want to do and work they have to do, and this can lead to greater burnout.

Personal Characteristics

Although job variables and the organizational context are the prime predictors of burnout and engagement, a few personality variables have shown some consistent correlational patterns. In general, burnout scores are higher for people who have a less hardy personality, who have a more external locus of control, and who score as neurotic on the Five-Factor Model of personality. There is also some evidence that people who exhibit type A behavior (which tends to predict coronary heart disease) are more prone to the exhaustion dimension of burnout.

There are few consistent relationships of burnout with demographic characteristics. Although higher age seems to be associated with lower burnout, it is confounded with both years of experience and with survival bias (i.e., those who survive early job stressors and do not quit). Thus, it is difficult to derive a clear explanation for this age pattern. The only consistent gender difference is a tendency for men to score slightly higher on cynicism. These weak demographic relationships are congruent with the view that the work environment is of greater significance than personal characteristics in the development of burnout.

Implications for Interventions

The personal and organizational costs of burnout have led to the development of various intervention strategies. Some try to treat burnout after it has occurred, while others focus on how to prevent

burnout by promoting engagement. Intervention may occur on the level of the individual, workgroup, or entire organization. At each level, the number of people affected by an intervention and the potential for enduring change increase.

The primary emphasis has been on individual strategies to prevent burnout, rather than social or organizational ones. This is particularly paradoxical given that research has found that situational and organizational factors play a bigger role in burnout than individual ones. Also, individual strategies are relatively ineffective in the workplace, where the person has much less control of stressors than in other domains of his or her life. There are both philosophical and pragmatic reasons underlying the predominant focus on the individual, including notions of individual causality and responsibility and the assumption that it is easier and cheaper to change people instead of organizations.

Recently, the range of options for intervention has expanded, given the recognition of (1) aiming for the positive goal of promoting engagement and (2) using the six areas of work life to better identify the critical intervention targets. These options have now been incorporated into both individual and organizational strategies, all of which focus on the job context and its impact on the people who work within it.

Glossary

EF-hand proteins

A family of diverse proteins that bind Ca^{2+} with high affinity. The EF-hand motif refers to α -helical parts of these proteins that form the Ca^{2+} binding site(s).

Calbindin is one of several EF-hand proteins found in the central nervous system with no clearly established physiological function.

The interest in this protein stems from the fact that it is selectively expressed in certain groups of hippocampal and cerebral cortical nerve cells, which appear to be relatively resistant to Ca^{2+} -mediated neurotoxicity. Furthermore, the levels of calbindin in the brain as well as other tissues are regulated by steroid hormones, including glucocorticoids and estrogens.

Ca^{2+} -mediated toxicity has been proposed to be important for the neurotoxic effects of glucocorticoids. According to the hypothesis put forward by R. M. Sapolsky, corticosteroids make nerve cells vulnerable to increases of intracellular free Ca^{2+} induced by excitatory amino acids. This is particularly evident in the CA1 area of the hippocampus. Sapolsky and coworkers have also postulated that this area of the hippocampus is important for the termination of the stress-induced increase of plasma cortisol. Thus, if CA1 neurons are damaged by high levels of plasma corticosteroids, this may lead to a vicious positive feedback cycle progressively destroying the

hippocampal target neurons of glucocorticoids and thus leading to a decline in cognitive function due to chronic stress.

In addition to the buffering of intracellular Ca^{2+} , overexpression of calbindin also reduces plasma membrane Ca^{2+} currents. Collectively, these actions would have beneficial effects in combating Ca^{2+} -mediated toxicity. Nonetheless, a lot more needs to be learned about the cellular functions of calbindin.

Calcium in the Extracellular Fluid
Intracellular Calcium

Glossary

<i>Heterotrimeric G-proteins</i>	Proteins that consist of three subunits (α , β , γ) and couple cell surface receptors to their effector enzymes. On the activation of cell surface receptors by their ligands, heterotrimeric G-proteins dissociate into the α subunit and the $\beta\gamma$ complex, both of which regulate the activity of effector enzymes such as adenylyl cyclase in the cell membrane.
<i>Second messengers</i>	Chemicals that are generated by extracellular stimuli arriving at the cell surface and that transduce the extracellular signal toward the interior of the cell.

Calcium ions are ubiquitous second messengers in biological systems.

Calcium in the Extracellular Fluid

Calcium is found in several compartments of the body. Extracellular Ca^{2+} is in an ionized as well as a protein-complexed form. There are G-protein-coupled cell surface receptors in several cells of the body that respond to ionized Ca^{2+} concentrations above 1.5 mM. These receptors activate the polyphosphoinositide cycle through the coupling protein G_q and may inhibit adenylyl cyclase through G_i or G_o . Apart from the parathyroid gland, where these receptors control the secretion of parathyroid hormone, the role of the G-protein-coupled Ca^{2+} sensor remains to be explored. It is, however, clearly expressed in the brain as well as the adenohypophysis, where corticotropes appear to express this receptor.

Intracellular Calcium

Inside cells, Ca^{2+} is found in several pools (e.g., smooth endoplasmic reticulum and mitochondria) maintained by various transporter proteins and intracellular ion channels. Intracellular free Ca^{2+} is

fundamental for a multitude of regulatory processes, including intracellular signal transduction.

The action of proteins induced by glucocorticoids in hippocampal neurons and anterior pituitary corticotrophs appears to require intracellular Ca^{2+} . Glucocorticoids augment Ca^{2+} influx through voltage-operated ion channels in the CA1 hippocampal neurons and increase the level of L-type Ca^{2+} channel subunit mRNA in this system. In pituitary corticotroph cells, blockade of the Ca^{2+} -activated protein phosphatase calcineurin markedly reduces the efficiency of glucocorticoid feedback inhibition of adrenocorticotrophic hormone release.

Glucocorticoids enhance the vulnerability of hippocampal neurons to Ca^{2+} -induced neurotoxicity. Thus, prolonged hypercortisolemia, such as that seen in chronic stress, Cushing's disease, or depression, may lead to neuronal loss in the hippocampus. Further, this mechanism may also contribute to the decline of mental function during aging because plasma cortisol levels are known to rise with age. This has led to the glucocorticoid cascade and to the calcium hypotheses of aging.

Glossary

Ischemia and/or anoxia

The brain is highly vulnerable to disturbances of the blood supply. Interruption of the blood supply (ischemia) or the delivery of blood containing an inadequate amount of oxygen (anoxia) leads to cell death as an area of the brain is deprived of oxygen, glucose, and other nutrients and the build up of carbon dioxide, lactic acid, free radicals, and other metabolites. Within a few minutes, the most severely damaged cells die by necrosis, and the area of damage is said to be infarcted. This is the process that underlies a stroke when the blood flow to the cerebral cortex and striatum is compromised by reduced blood flow in the middle cerebral artery.

Necrosis

An explosive event caused by exposure to a catastrophic toxic event characterized by almost instantaneous membrane lysis and the release of the intracellular contents into the extracellular space followed by an essentially inflammatory process. In ischemic tissue, glucose and glycogen are depleted within minutes, which leads to a fall in phosphocreatine levels and ATP with an inevitable failure of energy-dependent ion transporters

Apoptosis or programmed cell death

and a loss of ion homeostasis. The passive entry of water into the energy-depleted cell causes intense swelling and osmolytic damage that is sufficient to destroy the cytoplasmic organelles and the nuclear membranes.

In contrast to necrosis, apoptotic cell death is an active and controlled process characterized morphologically by the maintenance of membrane integrity until very late in the death process. The cell membrane shows characteristic blebbing as the cell volume decreases. The nuclear proteins condense to form an easily recognized pattern, the intracellular organelles are well preserved, and the whole still-intact cell is engulfed by phagocytes. The packaging and removal process serves to minimize inflammation. However, under conditions in which the phagocytic step is omitted, cells undergo secondary necrosis and rupture, spilling their contents into the surrounding tissue space.

Free radicals

When the blood supply or oxygen supply is compromised, toxic chemical species are formed that cause cell death either directly or by a process known as lipid peroxidation. The free radicals include a reduction of molecular oxygen to the superoxide anion (O_2^-), the formation of hydrogen peroxide (H_2O_2), hydroperoxy radicals (HOO^*), hydroxyl radicals (OH^*), and singlet oxygen (1O_2) species. Reactive metabolites and free radicals formed under anoxic or ischemic conditions set off a cascade of membrane destruction that also releases cytotoxic species known as lipid peroxy radicals (ROO^*) and hyperoxides ($ROOH$). In normally perfused and oxygenated tissue, lipid peroxides and other reactive species are usually dealt with effectively by specific enzymes that require the presence of vitamin E and a variety of other compounds present in a normal diet known as antioxidants.

Lipid peroxidation

For at least a decade, a rise in intracellular Ca^{2+} concentration ($[\text{Ca}^{2+}]_i$) has been considered one of the most important factors in the final common pathway that leads to cell death, whether by necrosis or apoptosis. Direct activation of calcium-dependent lytic enzymes including proteases, lipases, and nucleases, lipid peroxidation, damage to DNA, and rupture of mitochondria and cell membranes destroy cell structure. Accumulation of calcium phosphate within mitochondria disrupts these organelles, leading to impaired ATP production and, indirectly, further disruption of Na^+ exchangers. Disruption of mitochondria may also trigger apoptotic programs that lead to the death of adjacent groups of cells. The area of damage may be enlarged by the activation of nitric oxide synthetase and free radical production. Thus, calcium-dependent excitotoxicity plays a key role in many acute diseases of the central nervous system (CNS), including ischemic stroke and head injury, and may well be responsible for neuronal death following convulsions and the slow death of neurons in chronic diseases such as Parkinson's disease and motoneuron disease. Indeed, a similar mechanism may be triggered in Alzheimer's by the accumulation of extracellular amyloid.

Excitatory Amino Acid Neurotoxicity

A common cause of calcium-mediated cell death is the excessive release of excitatory amino acids. During normal synaptic activity, the local $[\text{Ca}^{2+}]_i$ is assumed to increase transiently following the episodic activation of excitatory amino acid receptors during synaptic activity. Although in the past this was thought to occur principally due to the entry of Ca^{2+} through *N*-methyl-D-aspartate (NMDA) receptor/ion channels, Ca^{2+} entry is now known to occur through a number of the AMPA (α -amino-3-hydroxy-5-methyl-isoxazole) receptor subtypes and kainate receptors. Recently, relatively modest synaptic stimulation has been shown to lead to local increases in $[\text{Ca}^{2+}]_i$ following the activation of metabotropic receptors and the subsequent release of Ca^{2+} from the endoplasmic reticulum. Following the massive release of glutamate induced by ischemia and/or anoxia, the overactivation of these same excitatory amino acid receptor pathways leads to increase in $[\text{Ca}^{2+}]_i$ enhanced by the opening of voltage-activated Ca^{2+} channels. The substantial depolarization that accompanies the excessive activation of the excitatory amino acid receptors also leads to excessive levels of $[\text{Na}^+]_i$. In turn, high $[\text{Na}^+]_i$ impairs the sodium-calcium exchanger, leading to further increases in $[\text{Ca}^{2+}]_i$. Given the abundance of excitatory amino acids in the CNS, it is easy to imagine that the release of glutamic acid from the cytosol of dead or degenerating

neurons will lead to the death of adjacent tissues. Additional factors may affect the ability of the neurons to resist the rise in $[\text{Ca}^{2+}]_i$, such as aging and the consequent impairment of DNA repair mechanisms, energetic impairment, environmental toxins, or viral infections.

Dysregulation of Calcium Homeostasis

In order for localized rises in intracellular calcium concentrations to efficiently activate enzymes and nearby ion channels in an ordered way, the overall calcium concentration must be kept at a low level of about 100 nM. Thus, the levels and the location of Ca^{2+} are tightly controlled by a complex interplay of inward and outward fluxes, buffering, and internal storage. However, during anoxia and excitotoxicity, these mechanisms either cease to operate or are overwhelmed, and $[\text{Ca}^{2+}]_i$ rises to a level that triggers inappropriate enzymes either directly or through the formation of free radicals and other toxic species. Although Ca^{2+} overloading is unlikely to be the sole mechanism mediating neuronal cell death, several lines of evidence link Ca^{2+} influx and neuronal injury. However, recent work suggests that the route of entry is also important and that Ca^{2+} entry following exposure to glutamate is a more significant cause of cell death than Ca^{2+} entry through voltage-sensitive Ca^{2+} channels. Thus, the possibility exists that the enzymes and/or substrates of the initiators of cell death may be colocalized with NMDA receptors. For instance, there is work to show that suppressing the protein PSD-95 selectively attenuated Ca^{2+} -activated nitric oxide (NO) production and specifically reduced NMDA-mediated neurotoxicity. Thus, targeting PSD-95 could have therapeutic potential.

The failure of several clinical trials to demonstrate a protective role for glutamate receptor antagonists has led to speculation about alternative mechanisms that may promote neurotoxic Ca^{2+} influx during anoxia, perhaps in the absence of glutamate receptor activation. These include the reversal of the Na^+ - Ca^{2+} exchanger, the activation of ATP gated ion channels by a rise in extracellular ADP levels due to increased hydrolysis of ATP, the uptake of Ca^{2+} by mitochondria leading to the release of superoxide free radicals, and, more recently, the activation of acid-sensitive Ca^{2+} permeable ion channels.

Calcium-Dependent Glial Toxicity

Although it has been known for some time that glutamate transporters on astrocytes are responsible for most of the uptake of glutamate from the extracellular space, it is only comparatively recently that the importance of ionotropic glutamate receptors

on astrocytes and oligodendrocytes has been realized. Prolonged activation of these receptors leads to cell death, and the vulnerability of glial cells appears to be equal to that of neurons. Interestingly, glutamate toxicity on oligodendrocytes is in part mediated by a reduction in cysteine uptake leading to glutathione depletion and is blocked by antioxidants. However, the bulk of toxicity is mediated as in neurons by a disruption of $[Ca^{2+}]_i$ homeostasis. Thus, *in vitro*, permanent middle cerebral artery occlusion has been shown to cause massive oligodendrocyte cell death, and in some brain areas the glial cells appear to be more vulnerable than neurons. However, within days there is an increase in the number of oligodendrocytes in the tissue bordering the infarct. It is hoped that the appearance of these new cells is beneficial, if not a harbinger of functional recovery.

Neuroprotectants

Therapeutic attempts to attenuate the damage caused by a rise in $[Ca^{2+}]_i$ focused on excitatory amino acid receptor blockade have failed. In the main, Ca^{2+} channel antagonists have proved disappointing. However, drugs such as riluzole, lamotrigine, and gabapentin are thought to limit glutamate release and/or block Na^+ channels. In more chronic situations, antioxidants may prove useful. Other studies have suggested that neurotrophic factors such as glial-derived growth factor, neurotrophin-3, cardiotrophin, and insulin-like growth factor and immunophilin antagonists may all be neuroprotective. Clearly, the possibility that $[Ca^{2+}]_i$ can also trigger apoptosis may lead to the discovery of new treatments. Although targeting the caspases, the final mediators of cell death, has proved ineffective, intervention at an earlier stage in the apoptotic pathway, at the level of the mitochondria, may promote neuronal and glial cell survival.

Glossary

<i>Allostatic load</i>	The physiological burden undertaken by the body to maintain allostasis, or internal stability, through environmental change evoked by a series of stressors.
<i>Glucocorticoid</i>	A class of stress hormones that mobilize glucose into the blood.
<i>Hypothalamic-pituitary-adrenal (HPA) axis</i>	One of the major stress response systems in the body; designed to maintain adequate glucose in the blood to help the brain and muscles respond to stressors.
<i>Psycho-neuroimmune connections</i>	The relationship among the mind, brain, and components of the immune system.
<i>Psychosocial factors</i>	Psychological and social factors that affect cancer patients or may be a component of supportive care.

Mind–Body Interactions and Cancer

Cancer research has productively focused on the pathophysiology of the disease, emphasizing aspects of tumor biology as predictors of disease outcome at the expense of studying the role of the body's psychophysiological reactions to tumor invasion. These reactions are mediated by brain–body mechanisms, including the endocrine, neuroimmune, and autonomic

nervous systems. Although a large portion of the variance in any disease outcome is accounted for by the specific local pathophysiology of that disease, some variability must also be explained by host-resistance factors, which include the manner of response to the stress of the illness.

That the stress of cancer is felt psychologically is indicated by the fact that as many as 80% of breast cancer patients report significant distress during initial treatment. Estimates of the prevalence of psychiatric disorders among newly diagnosed cancer patients has ranged from 30 to 44%, and 20–45% of patients exhibit emotional morbidity 1–2 years later. Even though the majority of women diagnosed with breast cancer do not meet the criteria for a psychiatric diagnosis, the vast majority experience the diagnosis of cancer as a major stressor, and 10% have severe maladjustment problems as long as 6 years later. Thus, breast cancer is a disease that causes considerable psychological stress.

Stress and Cancer Incidence and Progression

There is mixed evidence regarding whether social stress, such as divorce, loss of a job, or bereavement, is associated with a greater likelihood of incidence or relapse of cancer. Three recent meta-analyses have reached rather different conclusions. The first, which relied heavily on the European literature, concluded that stress has no effect on cancer incidence. It also reported that bereavement had no effect among 11 studies (odds ratio, OR, 1.06; 95% confidence interval, CI, 0.95–1.18, not significant) but that other stressors had a twofold effect (OR 2.63; 95% CI 2.34–2.96). However, the researchers based their final null conclusion on six studies they deemed to be of higher quality because of the use of population controls, blinding of interviewers to disease status, and other methodological issues. In these six studies, stress had no effect on cancer incidence. Although this meta-analysis clearly raised important questions about the stress–cancer link, it did so only after dismissing the findings of the majority of studies in the field. The second meta-analysis found that both stressful life events, in general, and those that involve loss and separation, in particular, are associated with breast cancer incidence. The authors of the third meta-analysis reported a modest yet statistically significant association between exposure to stress and

the incidence of breast cancer, although they suggested that this association may be an artifact of publication bias.

It may well be that the factors that influence cancer progression are quite different from those affecting incidence. Although this may seem counterintuitive because the tumor burden is much greater as disease advances (by the time of death, a typical cancer patient may have approximately 1 kg of tumors in his or her body), the setting of disease progression is one in which physiological resources are stretched to their limit due to the higher tumor burden and cumulative effects of disease-related distress and disability. Even minor variations in somatic response to stress may have an effect on disease course at this point.

A large prospective study in Finland involving 10 808 subjects found that major life stressors such as divorces or death of a loved one in the preceding 5 years predicted a significantly elevated risk of subsequent breast cancer. However, another study found that reports of subjectively evaluated stress actually predicted lower subsequent breast cancer incidence. One way to interpret this apparent inconsistency in the literature involves the difference between experiencing and reporting stress. Given that the literature associates the repression of distress with a possibly elevated cancer risk, the studies of reported stress classify repressors with those subject who report no stress and therefore as being potentially at a higher cancer risk than if they actually had experienced objective stressors. Clearly more research is needed in this intriguing area.

Coping Style and Cancer Incidence and Progression

Coping-style variables that have been associated with higher cancer incidence include anger suppression and restrained aggression and introversion. Variables associated with slower progression include fighting spirit, expressed distress, assertive uncooperativeness, and assertiveness (being non-type C). Being emotionally reserved has been found to increase substantially the risk of mortality (odds ratio of 3.9) among lung cancer patients as well. Although the solidity of the evidence for these relationships varies, it is of interest that the styles putatively associated with cancer incidence and more rapid progression are similar emotional suppression and nonassertiveness.

Antoni and Goodkin found that a passive coping style is related to the promotion of cervical neoplasia. In another study, they also found that breast cancer patients were more likely to employ a repressive coping style than noncancer patients. Measures of this construct (repression/sensitization as a defensive

style) have been reported as accounting for as much as 44% of the variance in the progression of breast cancer. Although stress may weaken the body's capacity to resist the progression of cancer, coping well with stress may counteract this effect. Work on psychological stress suggests that lack of control is a key factor in the magnitude of the physiological stress responses. People who feel helpless in response to stress may exhibit more exaggerated physiological evidence of stress, whereas those with greater self-efficacy in coping may dampen the effects of stress. In breast cancer patients, the belief that they could control the course of disease was significantly associated with good adjustment. Indeed, several studies have shown that it is not so much the intensity of the stressor as its perceived controllability that determines its effects. Changes in coping styles have been associated with changes in immune function, even over periods of less than a month. For example, in a study of the effects of emotional disclosure, subjects who discontinued their avoidance and engaged more fully in discussions of a stressful or traumatic topic exhibited decreases in antibody titers to the Epstein-Barr virus, indicating more successful surveillance of the latent virus by lymphocytes.

Expression, rather than suppression, of emotion has been postulated to reduce stress by discharging physiological arousal. Stress-related immune fluctuations due to the threat or onset of illness have also been shown to be reduced in those with an increased ability to cope with changes in their life through assertive communication. Active coping through openly expressing concerns and emotions is one factor that may influence the endocrine and immune alterations that may be related to disease progression.

Social Support as a Stress Buffer

Psychosocial treatments appear to buffer the effects of stress on endocrine function. For example, one intervention study found that biofeedback and cognitive therapy were associated with reduced cortisol levels in newly diagnosed breast cancer patients. Social support provided by the intervention may ameliorate the effect of stress on endocrine function. Indeed, providing social support during stress can profoundly alter the endocrine consequences of the stressor. Levine modeled this effect in squirrel monkeys. Although the animals produced large elevations in plasma cortisol concentrations when they were stressed when alone, stress-induced elevations were reduced by 50% when animals had one friend present and they disappeared when five friends were present. Thus, interventions that provide social support have the potential to ameliorate endocrine stress responses.

Thus, the social environment can have a buffering effect on stress. Being socially embedded is associated with less autonomic arousal than social isolation. Indeed, social connection has profound consequences for health. Being well integrated socially reduces all-cause age-adjusted mortality by a factor of two, approximately as much as having low versus high serum cholesterol levels or being a nonsmoker. Furthermore, people's positions in the social hierarchy (including relatively higher status even within the same social class) have health consequences. People are statistically more likely to die after than before their birthdays and important holiday, which are usually important times for social bonding and companionship.

Thus, the presence of adverse emotional events such as traumatic stressors seems to have negative potential health consequences, whereas good social relations seem to be associated with positive health outcomes.

There is evidence from 5 of 11 published randomized trials that psychosocial support is associated with longer survival for patients with breast cancer, malignant melanoma, and lymphoma. One component of the effective interventions is dealing directly with emotional distress associated with fears regarding disease progression.

There is evidence that resilience to stress, including disease-related distress, is associated with emotional style. Indeed, finding meaning in the midst of experiencing a distressing situation has been linked with a positive psychological state. Better adaptation does not involve being persistently upbeat or rigidly maintaining a positive attitude but, rather, dealing directly with negative affect as well. Positive and negative emotions are not merely opposite sides of a single dimension. The suppression of negative emotion tends to reduce the experience of all emotion, positive and negative. There is evidence that breast cancer patients who express more negative emotion (including anger and uncooperativeness) or realistic optimism (fighting spirit) may live longer.

Physiological Mechanisms of Stress and Support-Related Effects on Cancer Progression

Identifying the physiological mechanisms by which emotional expression and social support may influence survival time for patients with cancer is an intriguing problem. Possibilities range from body maintenance activities such as diet, sleep, and exercise to interactions with physicians and better adherence to medical treatment regimens to stress and support-mediated effects on endocrine and immune

function. These systems, which are part of routine somatic control and maintenance functions in the body, are influenced by psychological and social variables and are also involved in host resistance to tumor progression.

There is a long history of research linking stress to increased cancer risk. In a series of classic experiments, crowded living conditions accelerated the rate of tumor growth and mortality in rats. In an authoritative 1998 review of the human stress literature, McEwen documented the adverse health effects of cumulative stressors and the body's failure to adapt the stress response to them. The activation of the HPA axis is an adaptive response to acute stress, but over time, in response to cumulative stress, the system's signal-to-noise ratio can be degraded so that it is partially on all the time; this leads to adverse physiological consequences, including abnormalities in glucose metabolism, hippocampal damage accumulation of abdominal fat, and depression. Depression has been associated with more rapid cancer progression in 19 of 24 recent studies, although it has little relationship to cancer incidence. Abnormalities of HPA axis function, including glucocorticoid receptor hypersensitivity, have also been found to be associated with posttraumatic stress disorder. Thus, adverse events ranging from traumatic stressors to cumulative minor ones and responses to them, including depression, are associated with HPA axis dysregulation. Persistently elevated or relatively invariant levels of cortisol may, in turn, stimulate tumor proliferation. Possible mechanisms include the differential glucocorticoid response of normal and tumor tissue to glucocorticoid signals to secrete glucose into the blood, the activation of hormone receptors in tumors, and immunosuppression. Indeed, glucocorticoids are potentially immunosuppressive, so the effects of acute and chronic stress and hypercortisolemia may include functional immunosuppression as well, as has been shown extensively in animals. There is a growing body of evidence of stress-induced immunosuppression in humans as well. This, in turn, could influence the rate of cancer progression.

Stress Reactivity and Disease Progression

Allostatic load has been defined as the price that the body has to pay for maintaining allostasis (stability through environmental change). Recently, it has been suggested that increased allostatic load, which may occur through the cumulative build-up of stress over a lifespan, may significantly hinder the functioning of different physiological systems. Cancer itself constitutes a series of stressors: the threat to life and health,

the disruption of social activities, and the rigors and side effects of treatment. A given individual's psychological and physiological response pattern to stress in general is likely to be exacerbated by the diagnosis and treatment of cancer, thereby intensifying mind-body interactions mediated by the stress response system.

Reactivity to stressors involves not only the initial response but also the system's ability to reset itself after stress. Older organisms seem to reset themselves after a stressor less readily, leaving stress response systems more tonically upregulated for longer periods of time after cessation of the stressor. Cancer particularly affects older people, and chronic disease-related stressors are likely to further decrease the flexibility of stress response mechanisms. Sapolsky and colleagues found that stressed older animals not only had persistently elevated cortisol levels after the stress was over but also had much more rapid growth of implanted tumors. This finding was confirmed in a Ben-Eliyahu and coworkers, who also identified the suppressive effects of stress hormones on natural killer (NK) cells as one potential mediator of the effect. The magnitude of stress-induced elevation of corticosteroids may not be as important in cancer outcomes as the duration or persistence of the elevation.

Circadian Rhythm Disruption, Stress, and Cancer

Recurrence or metastasis of cancer can be considered a severe chronic stressor. Both short-term and long-term alterations in psychological state (e.g., major depression) are known to be correlated with endocrine changes. Stress is associated with increased sympathetic nervous system (SNS) and HPA axis activity. Catecholamines and cortisol (released during SNS and HPA axis activity) are elevated in cancer patients as well as in bereaved and depressed subjects. Abnormalities in the circadian rhythm of cortisol have been observed in subjects undergoing psychological stress (e.g., depression, unemployment, and posttraumatic stress disorder) and some types of physical stress (e.g., shift work and excessive workloads). Studies in humans by Sephton and coworkers and in animals by Filipski and coworkers have shown that abnormal diurnal patterns of cortisol (which is typically four to five times higher in the morning on waking than in the evening in humans) predict earlier cancer mortality. Furthermore, women who engage in nighttime shift work are at higher risk for developing breast cancer. Thus, the disruption of circadian patterns of sleep and related hormones, including cortisol and melatonin, are associated with an elevated risk of cancer incidence and progression.

Psychoendocrinology and Cancer

There are considerable data indicating that the HPA axis constitutes a likely connection between psychosocial factors and disease progression. Stress is processed through central nervous system (CNS) neurotransmitter systems such as norepinephrine, dopamine, and endorphins, which regulate hypothalamic releasing factors such as corticotropin releasing hormone (CRH), pituitary hormones such as prolactin and adrenocorticotrophic hormone (ACTH), and, through these, adrenocortical steroids and medullary hormones. Cortisol is the classic stress hormone; it is elevated in response to stress for prolonged periods and is immunosuppressive.

The role of endogenous corticosteroids in breast cancer progression is worthy of further exploration because (1) steroid hormone levels are responsive to psychosocial stressors through the HPA axis via CRH, ACTH, and the response of the adrenal in producing them and (2) because breast cancer is a hormone-sensitive tumor, as evidence by the effectiveness of steroid receptor blockers such as tamoxifen in delaying progression. Although the specific receptors blocked involve estrogen and progesterone, cross-reactivity with androgenic steroids and the dedifferentiated state of tumor tissue make corticosteroids of potential interest.

High levels of stress hormones such as cortisol may be associated with worse disease prognosis because breast cancers are often hormone-sensitive. In a study of patients operated on for breast and stomach carcinoma, the failure of morning cortisol levels to decrease within 2 weeks after admission was associated with shorter survival times. Direct evidence for effects of the HPA axis in the development of breast cancer comes from a study in which high serum levels of dehydroepiandrosterone (DHEA), a correlate of HPA axis activity, predicted the subsequent development of breast cancer 9 years later in normal postmenopausal women who had donated blood for a serum bank. Thus, correlational evidence suggests that physiological stress responses associated with poor adjustment to cancer may, indeed, speed disease progression.

Mechanisms have been proposed whereby the neuroendocrine correlates of stress may promote neoplastic growth. Stress hormones may suppress immune resistance to tumors or act via differential effects on gluconeogenesis in healthy versus tumor cells. Tumor cells may become resistant to the catabolic action of cortisol, which inhibits the uptake of glucose in numerous cell types. In such cases, energy is preferentially shunted to the tumor and away from normal cells by cortisol. Several studies found an association between

the stress-related elevation of glucocorticoids and more rapid tumor growth in animals. Another hypothesis suggests that hormones of the HPA axis may actually promote the expression of breast cancer oncogenes. In addition, because stress-related increases in SNS and HPA axis activity are known to have generally suppressive effects on immune function, it is certainly plausible that immune functions important in resistance to breast tumor growth are thereby suppressed. The elevation of glucocorticoids is associated with clinically significant immunosuppression, and the enhanced secretion of norepinephrine during stress has also been associated with suppression of lymphocyte function.

Other hormones that are elevated by stress, such as prolactin, growth hormone, and thyroid hormones, may also influence the course of disease. Prolactin is of special interest because of its role as both a tumor promoter and a stress hormone. There is evidence that a majority of breast carcinomas have prolactin receptors and that the presence of prolactin stimulates the growth of such tumors in tissue culture at physiological levels, perhaps by stimulating the development of estrogen receptors. Prolactin has been found to stimulate prostate carcinoma growth as well. Indeed strong positive correlations between prolactin and both estrogen and progesterone receptor levels in breast tumors have been noted. The surgical stress of radical mastectomy results in transiently elevated serum prolactin levels, perhaps through the removal of target tissue and a disruption in feedback mechanisms. Prolactin levels rise in response to other stressful stimuli as well. Because other pituitary hormones such as ACTH clearly reflect stress, it is possible that prolactin secreted in response to stress can thereby promote tumor growth. Thus, there is evidence for facilitative effects on tumor growth by stress hormones via several different mechanisms. Acute medical illness is associated with the increased secretion of ACTH and cortisol, and surgical stress is associated with lower DHEA/cortisol ratios (i.e., a combination of relatively low DHEA and relatively high cortisol levels) and higher prolactin levels.

Psychoneuroimmunology and Cancer

Many of these hormones are immunosuppressive when elevated. In spousal bereavement, cortisol levels are elevated, whereas NK cytotoxicity is decreased. Furthermore, there is no reason why disease-related stresses, including social isolation, death anxiety, pain, and sleep disturbance, should not affect immune function at the clinically observable level, for example in defenses against the progression of viral

infection. Yet little is known about these mechanisms or their effects on clinical infection. Cohen showed that vulnerability to systemic infection by rhinovirus is significantly mediated by stress and that people with larger social networks are less susceptible to viral infection. This model might well apply as well to vulnerability to cancer progression.

There is a growing body of research that provides evidence of associations between psychological factors and immune function. The work of the Glasers has shown that subjects experiencing such stressors as being a caregiver for an Alzheimer's patient, undergoing divorce or bereavement, or being in a poor relationship have been shown to have greater distress and lower helper/suppressor cell counts and ratios, lower total T-lymphocyte numbers, lower NK cell activity, and poorer response to Epstein-Barr virus.

Further evidence comes from work showing that immune organs such as the spleen are heavily innervated and that there are receptors for a variety of neurotransmitters on the cell membranes of lymphocytes. Stress hormones are known to influence cell adhesion molecules on lymphocytes, providing a possible mechanism by which stress may alter lymphocyte trafficking and therefore immune function. There is good evidence for this hypothesis in work by Dhabhar, who demonstrated that stress and the circadian corticosterone rhythm induce significant changes in leukocyte distribution in animals. Moreover, he showed that acute stress significantly enhances a cutaneous delayed-type hypersensitivity (DTH) response (an *in vivo* measure of cell-mediated immunity). In contrast, chronic stress significantly suppresses DTH responses, and stress-induced trafficking of leukocytes to the skin may mediate these changes of immune function. Most interestingly, he was able to mimic the effects of acute and chronic stress on DTH responses by the administration of corticosterone at doses similar to physiological levels following either acute or chronic stress, suggesting that glucocorticoids may be an important mediator of DTH responses during stress.

Thus, there is growing evidence for links among psychological stress, glucocorticoid responses, and immunosuppression. In rats, for example, stress significantly decreased NK cytotoxicity, increased levels of cortisol and ACTH, and increased the metastatic spread of mammary tumor to lung tissue. In stage I and II breast cancer patients, higher perceived social support and active seeking of social support were related to increased NK cell activity, and lower NK cell activity has been shown to predict disease recurrence. Thus, psychological factors have been associated with changes in immune measures, and these changes are markers of cancer progression.

Psychosocial Interventions and Immune Function

Psychosocial treatments designed to improve coping and assist in stress reduction have been associated with improvements in both immune function and physical health in cancer patients. Supportive relationships seem to modulate stress-induced immunosuppression, for example, among medical students undergoing examination stress. Even the disclosure of traumas in journals has been associated with better immune function. Stress-related immunosuppression may be mitigated by active coping styles or social support. After a 6-week psychiatric intervention for newly diagnosed malignant melanoma patients conducted by Fawzy, α -interferon-augmented cytotoxic activity of NK cells was elevated in the intervention subjects 6 months later and a survival benefit was observed, although there was no direct relationship between changes in NK cell activity and survival time. NK cells are known to kill tumor cells of many different types when tested either *in vitro* or in animal studies and may be particularly prone to stress-induced suppression.

Immune Function and Disease Progression

It is not always clear whether changes in serum immune or endocrine measures are a cause of or result from changes in disease status. Indeed, the immune surveillance theory of cancer development and progression has been questioned. Cancer is not, after all, an immunodeficiency disease, and immunosuppressed patients such as those with acquired immunodeficiency syndrome (AIDS) are at higher risk only for rare cancers such as Kaposi's sarcoma. However, research in animals as well as humans suggests that immunosuppression may be a factor in the rate of disease progression, and *in vitro* measures of immune function that are salient to disease progression are affected positively by social support and adversely by stress.

There is evidence from nonclinical populations that social integration buffers against the stress-induced suppression of NK cell activity. It thus makes sense that the addition of intensive social support in groups for women undergoing substantial medical and other stressors might have a similar buffering effect. Thus, although definitive clinical links have not been made, there is evidence that NK cell activity is associated with the rate of breast cancer progression. This immune parameter, which is affected by stress and social support, also varies with disease progression, making it a reasonable candidate for investigations into the

mediators of the effects of group support on the rate of breast cancer progression.

Stress and Autonomic Responses

Cacioppo and colleagues examined the effects of psychological stress on autonomic responses including heart rate reactivity and cardiac vagal reactivity (as indexed by respiratory sinus arrhythmia reactivity). They found that individuals who demonstrated greater autonomic responses to brief laboratory stress also showed higher stress-related increases in ACTH and cortisol. Thus, autonomic tone may be a good index of the reactivity of the HPA axis to acute stress, and autonomic measures are less invasive than the repeated blood sampling that is required to measure short-term changes in HPA axis activity. The results of psychoneuroimmunological studies have shown that heart rate reactivity after a stressor was also related to changes in NK cell activity, suggesting that the measurement of stress-induced changes in autonomic tone may be of value in defining the possible mechanisms underlying psychosocial effects on immune function. Failures to mount a corticosteroid response to stress may place an undue burden on other stress response mechanisms, such as the autonomic nervous system. The loss of vagal tone is often seen in poor stress responders, leading to cardiovascular burden and possibly to immune effects as well. Autonomic tone has not only been associated with stress, but also with emotion regulation. Indeed, the baseline levels of cardiac vagal tone and vagal tone reactivity have been associated with behavioral measures of reactivity and the expression of emotion; thus, cardiac vagal tone can also serve as an index of emotion, and parasympathetic influences on heart rate may be influenced by emotional expression, for example as a means of coping with stressors.

Conclusion

The literature reviewed here provides evidence that people's manner of responding to disease-related stress may affect the rate of disease progression as well as their psychological adjustment. The stress response system is most effective when it is on when needed and off when it is not. Variance in the rate of cancer progression may be accounted for by more or less adaptive stress response systems. This effect of stress and stress response on cancer progression may be mediated by the endocrine, immune, or autonomic nervous systems or by some combination of the three. There is evidence that stress is a uniform part of the experience of cancer and its treatment, that various coping styles affect stress-mediated physiological

effects, and that these in turn may affect the somatic response to cancer progression. Furthermore, various psychosocial interventions have proven effective in enhancing coping with this stress, and some have demonstrated an effect on disease progression. This evidence suggests that assistance with stress management can contribute to effective cancer treatment.

The stress associated with the diagnosis and treatment of cancer can result in significant reductions in patient quality of life. Fortunately, numerous psychosocial interventions for patients with cancer have been found to be quite effective in assisting with such stress. Interventions, including education, stress management, coping skills training, and support, have resulted in notable improvements in the psychological and physical health of patients with cancer.

The Cancer Problem

Psychosocial Interventions

Intervention Outcomes

Conclusion

Glossary

Active-behavioral coping methods

Actions that an individual does that focus on dealing with problems and tend to make a person feel better in both the short and the long term.

Active-cognitive coping methods

Mental thoughts and techniques that focus on dealing with problems and tend to make a person feel better in both the short and the long term.

Avoidance methods

The behavioral and mental techniques that a person uses to feel better in the short term but that are not directed at solving problems and, therefore, fail to work in the long term.

The Cancer Problem

Cancer remains a significant health problem in the United States with over 1 million new cases reported each year. Although many patients still die from their cancer, major advances in medical care have occurred. Over the past 30 years, many patients have been cured and long-term survival for some types of cancer has increased significantly. Therefore, today's patient with cancer may be placed in one of three basic categories. The first category consists of patients who are cured and yet need to deal with a chronic fear of recurrence. The second category consists of cancer patients and includes those who are not cured but have a long-term prognosis; these patients must face dealing with a chronic disease. The third category consists of those patients who, despite medical advances, are terminal and must deal with death and dying.

Regardless of the category in which a patient finds him- or herself, the adverse psychological effects

associated with the diagnosis and treatment of cancer can be quite severe. Cancer is associated with high rates of emotional distress, which may include major depression, dysthymia, or adjustment disorder with depressed mood. Other possible affective responses to cancer are anxiety, anger, guilt, helplessness, hopelessness, denial, disbelief, and grief. In addition to such psychological effects, the diagnosis and treatment of cancer are often accompanied by adverse physical symptoms. These can include pain, insomnia, fatigue, shortness of breath, nausea and vomiting, and changes in appetite and activity. In addition, the stress associated with diagnosis and treatment is believed to negatively affect immune parameters and other somatic variables in patients with cancer.

Psychosocial Interventions

Fortunately, various psychological interventions have been developed to assist patients with cancer in dealing with diagnosis and treatment. A review of the literature over the past 20 years suggests that available interventions for the management of cancer-related stress include one or more of the following basic components: education, stress management (including behavioral training), coping skills training, and emotional support.

Education

The overall goal of education for the cancer patient is to replace the sense of helplessness and inadequacy due to uncertainty and lack of knowledge with a sense of mastery and control. Educational interventions not only offer diagnosis- and treatment-specific information to patients, but may also enhance adjustment and improve coping skills. Those interventions currently in use provide the cancer patient with information about his or her particular diagnosis and treatment side-effects, as well as how to manage the side-effects. Cancer prevention information and how to recognize the warning signs of new or recurrent cancers may also be taught. In addition, general education relevant to a healthy lifestyle is often provided. Such topics as good nutrition, exercise, immune functioning, and effective communication are but a few examples.

Stress Management

Because stress is associated with physical disease and illnesses (e.g., headache, gastrointestinal problems, heart disease, hypertension, and susceptibility to infections), it is logical to assume that making and sustaining even minor lifestyle changes that reduce

stress can improve the odds for better health and a better quality of life. Research has shown that a generalized decrease in stress allows patients to cope more effectively with the overall emotional impact of cancer, enhances compliance with medical regimens, and assists in the management of treatment side-effects (e.g., pain, nausea and vomiting, and insomnia). In such an intervention, patients learn how to recognize personal sources of stress and then how to eliminate or modify the source of stress through problem solving or a change in cognitive appraisal or attitude. Patients are also taught how to change their physiological response to the stressor by replacing it with a relaxation response. Such responses are learned through behavioral training and include the techniques of progressive muscle relaxation (PMR), deep breathing, meditation, biofeedback, hypnosis, self-hypnosis, guided imagery, yoga, and Tai chi.

Coping Skills Training

The goal of coping skills training is to teach the cancer patient how to deal with his or her diagnosis, treatment, and life in general using effective cognitive and behavioral methods. An example of such an intervention is one in which patients are introduced to three types of coping: active-behavioral, active-cognitive (both of which are usually effective coping methods), and avoidance (which is generally ineffective in the long term). Active-behavioral methods may include exercising, improving diet, using physical relaxation techniques, expressing feelings, going out more socially or treating oneself to an outing, and finding out more about the disease. Active-cognitive methods may include thinking about the illness 1 day at a time, praying and trusting one's belief in God or a higher power, accepting the reality of the diagnosis but not equating it with a poor prognosis, forming a mental plan of action, thinking more about the meaning of life and what is really important, using some kind of mental relaxation technique, and trying to maintain and use positive thinking. Avoidance techniques include self-blame; social isolation; procrastination; and tension reduction through eating, sleeping, drinking alcohol, smoking, or taking drugs more than usual. Following instruction, participants are often asked to apply these coping strategies to common theoretical problems and situations they have encountered (e.g., diagnosis, treatment issues, body image, communication, interpersonal relationships, anxiety/depression, and death). After discovering effective ways to deal with these theoretical problems through active-behavioral and active-cognitive means, patients are asked to apply the techniques to their own real-life situations.

Emotional Support

Interventions for patients with cancer can be delivered in individual, patient group, or family settings. Whatever the format, psychosocial interventions can be an invaluable source of support for patients with cancer. A safe environment provides patients with the much-needed opportunity to express the feelings they have about their disease and its treatment.

In group therapy, patients also have the opportunity to learn healthier ways of dealing with their illness from others in similar situations. The sense of community experienced through group participation provides patients with a new and important social network at a time when isolation is common and more emotional support is needed.

Individual psychotherapy is a long-established method that is also used to ease the distress and disruption that accompanies the diagnosis of cancer. Support, compassion, and empathy from a therapist form the cornerstone of such interventions.

Psychotherapeutic interventions have also been used to enhance family support. Improved communication; role flexibility; and adjustment to changing medical, financial, social, and vocational realities are targeted. An atmosphere of openness and shared problem solving in the family is associated with affective improvements in patients with cancer.

Combination Therapies

Research has shown that education, behavioral training, coping skills training, and support have been generally helpful when used separately but are even more powerful and enduring when used in combination, especially in a group format. The explanation for this success may be that patients are given multiple tools with which to cope. It may also be that different individuals come to the cancer experience with different coping skills and resources already available. In this case, their existing coping skills are reinforced and supplemented in those areas in which they are lacking. In addition, the group format provides tremendous emotional support and is more cost

effective than an individually delivered intervention. A summary of the types of interventions that have been proven helpful for patients with cancer is provided in [Table 1](#).

Intervention Outcomes

Over the years, the outcomes of psychosocial interventions for patients with cancer have yielded improvements in both psychological and biomedical functioning.

Psychological Outcomes

Educational interventions for patients with cancer have resulted in increases in knowledge about the disease and treatment compliance and decreases in anxiety and depression. Such interventions have also been shown to enhance coping skills. Behavioral training interventions have resulted in decreased anxiety, whereas supportive interventions, delivered in individual, group, and family formats, have been shown to reduce emotional upset, confusion, social isolation, and anxiety and depression and to improve quality of life, communication, coping skills, sleep, adjustment, body image, and self-concept.

Physical Outcomes

Both educational and behavioral training interventions have been shown to be effective in assisting the patient with cancer-related pain. Behavioral training has also been found to be quite helpful in reducing the frequency, severity, and duration of side-effects from chemotherapy (i.e., anticipatory nausea and vomiting). In fact, some studies demonstrate an increase in food intake as a result of such lowered physiological arousal.

Finally, a growing body of literature suggests that psychosocial interventions for patients with cancer may result in improvements in immune functioning and increases in recurrence-free intervals and survival rates. Behavioral training has been associated with decreased cortisol levels, elevations in immune system

Table 1 Effective therapies for the patient with cancer

<i>Education</i>	<i>Stress management</i>	<i>Coping skills training/ mechanisms</i>	<i>Support</i>
Diagnosis: test results, symptoms	Manage stress source	Active-behavioral (e.g., problem-solving)	Emotional support: expression, validation
Treatment: options, side-effects, dealing with effects	Manage stress reaction	Active-cognitive (e.g., cognitive restructuring)	Group therapy: disease specific, social network
Disease: recurrence, prevention	Eliminate/modify stressor	Avoidance (e.g., drinking or smoking more)	Individual therapy: patient specific
Health: nutrition, exercise	Relaxation response: PMR, meditation, deep breathing, biofeedback, hypnosis, guided imagery, yoga, tai chi		Family support: communication, role flexibility, adjustment

Table 2 A sampling of intervention outcomes

Category	Type of intervention	Results	Source
Psychological outcomes	Education	Decreased depression	Pruitt et al. (1993)
	Behavior training	Decreased anxiety	Gruber et al. (1993)
	Education, support	Increased effectiveness in dealing with psychosocial problems	Gorden et al. (1980)
Physical outcomes	Behavior training	Decreased anticipatory nausea	Arakawa (1997)
		Increased immune parameters	Lekander et al. (1997)
Combined outcomes	Education	Decreased pain intensity	de Wit et al. (1997)
	Support	Decreased emotional distress, reduced pain, increased survival rates	Spiegel et al. (1981, 1989)
	Education, stress management, coping skills training, support	Decreased emotional distress, enhanced coping, increased immune parameters, increased recurrence-free intervals and survival rates	Fawzy et al. (1993)

functioning, and improvements in immune parameters (e.g., natural killer cell activity and lymphocyte number and responsiveness). Supportive interventions and combination therapies involving follow-up assessments over many years have also demonstrated reductions in cancer recurrence and death rates for patients participating in such interventions. A sampling of intervention outcomes in patients with cancer is provided in [Table 2](#).

Conclusion

The emotional and physical stressors encountered by cancer patients are numerous and unique. Based on a review of the literature, cancer patients may benefit both biomedically and psychologically from a variety of psychosocial intervention programs. A structured, psychosocial intervention consisting of education, stress management, coping skills training, and group support offers the greatest potential for positively affecting emotional and physical functioning in patients with cancer. It should be noted that such psychosocial interventions need to be used as an integral part of competent, comprehensive medical care and not as an independent treatment modality for cancer.

Introduction

Stage I: Startle/Disorientation

Stage II: Disbelief

Stage III: Hypervigilance

Stage IV: Resistance/Compliance

Stage V: Depression

Stage VI: Eventual Acceptance

Comment

Introduction

Few life experiences are as difficult and challenging as being held hostage or as a political prisoner. In reviews of the literature and from my own clinical work dealing with former hostages and prisoners-of-war, six stages of adaptation to captivity became apparent. The time course over which these stages occur progressively lengthen from the first to the final stage. More specifically, the first stage lasts only seconds to minutes, whereas the next stage lasts minutes to hours. The third stage generally lasts a few hours to a few days, whereas the fourth stage lasts from several days to a few weeks. The fifth stage is protracted, lasting several weeks to a few months. Finally, the sixth stage can last from several months to a year or two. In the presentation that follows, a general description of each stage is given and mention is made of key captor and captive behaviors, along with useful coping techniques.

Stage I: Startle/Disorientation

The first stage lasts from seconds to minutes. The development of this stage is influenced greatly by the setting in which a captive is taken. Military personnel who are at high risk for capture as prisoners-of-war have often gone through intensive training on what they might encounter. Hostage takings are generally unanticipated and often life-threatening. A common theme in both groups is the abrupt transition from life as usual to sudden, often brutal, subjugation. Such a transition is impossible to assimilate quickly. Captives frequently experience extreme disorientation, seek possible means of escape, and have

anxieties for their lives and the lives of others during these first seconds to minutes.

Captors at this stage are generally highly excitable and fervently driven by political and/or ideological causes. Captives may well be at a loss initially about how to deal with them. To challenge the captors' actions, even by a scornful laugh, may lead to impulsive retaliation and possibly to execution.

Successful coping with capture is constrained by the extreme brevity of this stage. Captives should regain their orientation and control of anxiety as quickly as possible. Some captives cope with the initial shock in a dissociated state, feeling more like observers than participants. Others can be in a state of dazed shock, unable to take any immediate actions. The captives' ability to bring their minds into focus on the details of their surroundings, such as counting the number of captors or studying their behaviors, may greatly help to limit these acute responses to captivity stress.

Stage II: Disbelief

The second stage lasts from minutes to hours. Captives from Western countries, accustomed to protections under the law and an emphasis on human rights, may well respond with utter disbelief when they are suddenly thrust into a situation in which all personal freedoms are forcibly withdrawn. They may think, "This can't be happening," or "Surely we'll be rescued shortly." At some deeper psychological level, captives know that such expectations can be or are wrong, but these thoughts often persist during this stage.

The captors' behavior during this time can be tyrannical, with beatings and physical restraint. Dehumanization includes stripping away the captives' clothes and personal possessions, binding them, blindfolding them, and taking photographs of the subjugated captives for later propaganda use. Captives may even be tortured to obtain early confessions. The captors' plans for the captives are frequently unstable at this stage, with the group moving several times from one location to another being the typical scenario. The captives generally have little chance to communicate with one another, and their attempts to do so are likely to bring swift and painful retaliation.

Many prisoners cope with this stage by convincing themselves that conditions will improve shortly. Hopes for rescue may be sustaining, and sometimes rescue does occur. However, it is probably best for captives to try to escape their circumstances by turning their attention inward. Some captives engage in thoughts of retaliation, but it is more helpful for them to focus on

images of loved ones, valued friends, prayer, and other sustaining elements of life and freedom.

Stage III: Hypervigilance

The third stage lasts from hours to days. Although efforts by the captives to orient themselves to their new environments may start at the very beginning of captivity, the emergence of the hypervigilant stage releases unexpected talents of observation. Assessing mileage while being driven blindfolded, remembering labyrinthine pathways through city streets, and accurately keeping track of passing time are examples of such orientation skills that frequently emerge.

Captor behavior is usually unpredictable during the first days of captivity. The leaders of the captors are often confused about their ultimate goals and objectives. Generally, some form of interrogation begins, with an emphasis on intelligence gathering. Guards tend to be highly attentive to possible escape attempts during these early days of captivity.

Early in their incarceration, captives turn their hypervigilance to orienting tasks. Even when confined in a cell without daylight, nonvisual cues (changing of the guards, when meals are served, etc.) are gleaned to construct a 24-h cycle. The captives examine their surroundings in minute detail, including the behavior of their guards. They also structure their environment as much as possible – sandals placed here, the latrine bucket placed there, and so on.

A frequent mistake made by captives during this stage is to misinterpret bits of their captors' conversations that they overhear, particularly concerning the release of the captives. The captives' wishful thinking about an early rescue leads to the generation of false rumors and disappointment becomes inevitable.

Stage IV: Resistance/Compliance

The fourth stage lasts from days to weeks. This stage frequently begins when the captors begin to coerce the captives into cooperating with them; captors may demand that captives sign confessions of their crimes or make enforced public appearances to help dramatize the captors' achievements. Interrogations at this point change from intelligence gathering to exploitation. The degree to which a captive capitulates to these tactics depends on the severity of the torture applied combined with the captive's ability to resist coercion – which may include torture. It is clear from the literature that anyone can be forced to cooperate with his or her captors if sufficient physical and psychological torture is brought to bear. Nevertheless, people with strong character, and particularly those who have been trained to resist such demands, do much better than others without these assets.

The captors' behavior at this stage is so similar for all prisoner-of-war and civilian hostage situations that it is as if they all had read the same manual. The original architects of many of these behaviors were the secret police in Czarist Russia, with modifications later introduced by the state police in Nazi Germany. Asian refinements were added a decade later by North Korean military. These behaviors include intimidating arrests, imprisonment for indeterminate lengths of time, physical and nutritional deprivation, disturbances of body rhythms, physical and sensory isolation, deprivation of daylight, stressful (often brutal) interrogations, unpredictable responses from guards and inquisitors, frequent threats of death, and attempts to reeducate the captives.

Isolation appears to be the most stressful captor tactic, dreaded by many more captives than physical torture. The settings used are generally cramped, filthy, and pest-ridden. The captives are kept uncomfortably hot or cold, with poor lighting and ventilation. Communication with fellow captives, and even with guards, is usually prohibited. Finally, extremely few allowances are provided for personal hygiene. Periods of isolation may be alternated with friendly interrogations, especially if the captive becomes eager for human contact. Interrogations are almost always unpredictable as to timing (day or night), duration, and approach of the interrogator(s). The overall aim is to soften the captives' resistance and make them susceptible to the will of their captors.

The captives' behavior is highly variable. Some attempt to resist all coercive attempts until they are thoroughly beaten and broken, even to the point of death. Others prove to be unable to withstand even moderate deprivations without making major concessions. Most captives, however, learn to resist torture, isolation, and other deprivations until severe physical and/or psychological damage becomes a likely result of continued resistance. Then, they comply sufficiently for captors to suspend their tortures, giving the captive critical time to rest and recover. Providing clever admissions during interrogations, especially information that takes a long time to validate, can provide precious time for captives to replenish their physical and mental reserves.

One extremely important coping maneuver is physical fitness. Hours of physical training can be carried out even in extremely confined settings. Flexibility exercises minimize the risk of joint dislocations and bone fractures from ensuing torture sessions. Running in place promotes endurance conditioning, with attendant feelings of stress reduction and increased ability to sleep. Perhaps the most important coping activity is communication with fellow captives. The ingenuity of captives in passing voice, hand, tap, or other signals

to their cohorts is truly remarkable. By such methods, communication can be carried out even with people confined to isolation. To feel part of a supportive network of fellow sufferers provides immeasurable sustenance to a captive. Also of extreme importance is faith, prayer, and thoughts of loved ones.

Stage V: Depression

The fifth stage lasts from weeks to months. When captives begin to confront their several recent losses, particularly if they dwell on these losses, they frequently enter into depression. In reality, captives have lost not only their freedom and most everything else that they have valued in life, but they may have even also lost their future. Further, they are deprived of information about the outside world and are often misled by captors as to the degree of interest in their welfare shown by their own government and countrymen. Perhaps most cruel is the indeterminate length of stay in captivity. Prisoners-of-war sometimes reflect with envy on civilian prisoners who have finite prison sentences to serve.

Captives with depression may wish to spend most of their day in bed. Loss of appetite far exceeds the poor quality of the food provided in causing large weight losses. Communication between captives may be avoided even though opportunities for such interactions present themselves. The captives may also feel guilt over their performance during interrogations. Thoughts of suicide may become prevalent, but actual suicide attempts are rare.

The captives' coping with depression is aided enormously by a strong support group. Repeated documentation exists of the virtually life-saving influences of support people in the lives of depressed captives. One excellent coping skill is for captives to use their intellect constructively to combat the potentially devastating boredom. Even a single book can be read and reread, with new meanings found on each reading. Creative work, such as writing, can be extremely helpful. Even without these tools, captives can use their intelligence to elaborate future life plans that they want to achieve. One captive, deprived of paper and pencil, composed books of children stories in his mind and after his release wrote and published the stories. Humor has an immense coping value. Captives getting the best of their guards on occasion not only provides humorous remembrances that can be savored later but gives the captives a moment of control in what otherwise is a totally uncontrolled life situation.

Although nearly all captives experience depressive symptoms during this stage, for some the symptoms are mild and the duration is fleeting. Others become significantly depressed and, in addition, physically ill.

Figure 1 Former American hostages held in Iran ($N = 35$) found to be healthy 1 year after release were frequently healthy throughout captivity. None of the former hostages who reported being ill 1 year after release were healthy during captivity.

The most common physical symptoms are gastrointestinal, dermatological, cardiovascular (hypertension), neurological (headache), orthopedic (injuries), and respiratory. The number of symptoms that captives experience, provided their captivity experience was roughly the same as that of others, often reflects their susceptibility to stress. Figure 1 presents data on illness symptoms reported during and 1 year after captivity for 35 Americans held hostage in Iran. Of the 14 former captives who experienced significant mental and physical symptoms during the first year following their release from captivity, suggesting stress susceptibility, 100% of them also reported having had significant symptoms during captivity. Conversely, of the 21 former captives who reported good health during the first year following their release from captivity, suggesting a low susceptibility to stress, only 46% reported having had significant illness symptoms during captivity.

The captors' behavior at this point is generally limited to custodial care. Unless there is a continuing need for propaganda statements, interrogations are greatly reduced in number. The guards may be changed because the routine generates little excitement for the original captors; escape may become possible at this time, due to the laxity of the new guards. The captors may occasionally reassert their position of control by staging prisoner movements, issuing new policies, and so forth.

Stage VI: Eventual Acceptance

The sixth stage lasts from months to years. Until this stage, captives have actively resisted the idea of a prolonged incarceration. It is now clear that a release, or a rescue, is not likely to occur any time soon. Thus, this final stage of adaptation starts with the conviction that captives must make a more productive use of their time than waiting for rescue if they are to successfully tolerate their ordeal.

Much as a sailor steers a disabled ship by simply concentrating on one wave then the next, captives

find that it's best to live their lives one day at a time. Although they may dwell on the past, not much thought is given to a future more distant than tomorrow. Small things begin to take on huge importance. A frequent preoccupation of captives is what will be served, generally with rice, for the next meal. Meal times, exercise periods, bedtime, and so forth are carried out with compulsive regularity. Social niceties may disappear, and personal appearance may slide. Swearing and crude language can become the norm. Interpersonal difficulties often arise more from intolerance about how a roommate chews his food rather than from philosophical or political differences.

The passage of time becomes distorted. As characterized in Thomas Mann's famous novel, *The Magic Mountain*, although a single day may appear to progress very slowly, weeks and months seem to fly by. Captives have been amazed to find, on release, that they greatly underestimated the time they spent on various activities. The involvement in creative tasks makes time pass swiftly. A German prisoner-of-war, held along with Americans in Vietnam, composed a German-English-French dictionary. He used cloth from his prison pajamas for a book cover, charcoal and water for his ink, paper obtained from his captors, and foil from fellow prisoners' cigarette packets to insulate his book cover. When he was fully absorbed on this project he found that "There just weren't enough hours in the day."

The acquisition of new knowledge is assiduously pursued during long-term captivity. Some captives learn a second language from their cellmates. Others build homes in their imagination – board by board, nail by nail. One prisoner-of-war held in North Vietnam reviewed his entire schooling and found he could recall the names of every classmate, where each one had sat in class, the names of every one of his teachers, and even the subject matter they taught. Reading and writing are important coping activities. Even if they are never delivered, writing letters to family and loved ones is an enormous source of support for captives.

Group activities lend a vital cohesive force to the captive group. These activities range from church services and group games to theater and fitness activities. Even forced labor can become a sustaining activity, as is so aptly illustrated in Boulle's famous novel, *The Bridge over the River Kwai*.

The captors' behavior remains custodial in the main during this period. With the exception of re-education sessions given in some prisoner-of-war settings, captors are primarily concerned with keeping their victims alive and presentable as bargaining chips for future negotiations.

Comment

The emphasis in this report on the stages of adaptation to captivity is on the captives' stress. Very little has been studied about the stresses experienced by the immediate families of the captives. Certainly family members experience their own stages of adaptation, some of which are probably similar to those of captives. However, family members not only have to deal with loss of the captive, but they also must learn to deal with a nearly constant intrusion into their lives by the public and press. The families also need support groups. The success of such groups was demonstrated by the families of Vietnam prisoners-of-war and families of the Americans captured in Iran. These families developed support groups for enhanced communication, emotional solidarity, and political influence, and these associations proved to be extremely effective.

Introduction

Stage I – Brief Euphoria

Stage II – Hyperarousal

Stage III – Compliance/Resistance

Stage IV – Denial

Stage V – Restitution

Stage VI – Gradual Readjustment

Comment

Introduction

There are six stages of adaptation to captivity (see **Captivity, Adaptation to**); the time course over which these stages occur progressively lengthen from the first through the final stage, the initial stage lasting seconds to minutes, the next stage lasting minutes to hours, the third stage lasting the first hours to the first days, the fourth stage lasting the first days to the first weeks, the fifth stage lasting the first weeks to the first months, and the sixth stage lasting from the first months to the first years. The literature, along with my own experience, also suggests that recovery from captivity can be similarly summarized into these six stages.

Stage I – Brief Euphoria

The first stage lasts from seconds to minutes. Despite preconceived notions that the general public may have about how jubilant captives will be on release, a true rejoicing rarely materializes. Captives initially may feel euphoric, but this feeling is fleeting and any planned celebrations may fall flat. When ex-captives are returned to the United States by plane, the aircrew may have champagne aboard and decorations in place only to find that the celebration consists of a brief cheer on take-off followed a few seconds later by quiet conversations and individual contemplation.

Released captives' behavior is, in large part, guided by a deep suspicion that this release may amount to nothing more than another false hope. Emotional restraint and careful inspections of events are typical.

Ex-captives generally realize, however, that the public wishes a show of enthusiasm on their return, and they try not to disappoint it. This display, however, often tends to be hollow and fragile.

Stage II – Hyperarousal

The second stage lasts from minutes to hours. Hyperarousal at the second stage is appreciably different from the hypervigilance described during adaptation to captivity. In the hypervigilance stage, the captives' alertness is high, their observational powers are keen, and they are aware of even subtle cues regarding the behavior and motivations of their captors. In the hyperarousal state, returnees tend to be overstimulated and mentally slowed. The commotion around them, along with the great assortment of new stimuli, can render them punch drunk.

During this early stage of recovery, it is critical to protect former captives from overzealous politicians, well-wishers of all sorts, and particularly the press. Sensitive politicians will make their presence brief and depart shortly along with their entourage, well-wishers can be a significant problem in terms of crowd control, but most difficult to manage are members of the press. During the transition to freedom, former captives often have been severely sleep deprived. Yet, because returnees typically do not wish to offend any of the greeting party, they may talk at length with people who approach them.

If the period of captivity has been a long one, family members may have developed close friendships with representatives of the press. These family members may require repeated explanations as to the need to shield ex-captives from news media exploitation. In their vulnerable state, ex-captives may agree to interviews in which statements are made that they live to regret.

A treatment imperative, then, is to protect returnees from further exhaustion. Because physical examinations and psychological debriefings are often needed, the best place for these assessments may be a hospital with limited access to the public. In the case of the returned hostages from Iran, an Air Force hospital in Germany proved to be ideal for these purposes. The debriefings themselves had a positive effect for many ex-captives through the venting of strong emotions and the opportunity to obtain feedback on how they performed during captivity. The press and even family members were kept at the perimeter of the hospital. Although telephone

contact was encouraged between returnees and their family and friends, actual visits were discouraged. These restrictions allowed necessary medical examinations to be conducted in a restful and recuperative setting.

Stage III – Compliance/Resistance

The third stage lasts from hours to days. Initially returnees are likely to comply with most requests. They are, of course, accustomed to following orders from their guards and captors without much thought given to their own preferences. A danger, therefore, exists that health-care personnel may request too much. For example, ex-captives may complete hours of psychological testing or other paramedical activity not directly related to their immediate care without demurral. As the ex-captives begin to regain feelings of individual power, they start to resist such activities. Who is going to reprimand a noncompliant man or woman who has just returned from months to years of captivity stress?

The transition from compliance to resistance became obvious to physicians caring for the ex-hostage group released from Iran around the third hospital day. Initially, the former captives were extremely candid and cooperative. Most were grateful for the clinical interactions. Two to three days later, however, many started to become somewhat cavalier about keeping their appointments, began to skip ward routines, and stayed out past bedtime hours. Some limits has to be set. Early rehabilitation programs for Korean War POW, conducted as the men returned home aboard ship, were similarly disrupted.

Treatment plans should allow for this emerging independence. For example, some time from the hospital routine should be allowed for shopping, a meal out, and so forth. The hospital setting should not cause returnees to be treated as in-patients; ex-captives should wear leisure clothing instead of hospital pajamas. Doctors, nurses, and other health-care providers must watch their own countertransference reactions. Offering too much too soon and/or attempts to personally help the former captive make up for past deprivations can lead to unprofessional behaviors.

Allowing ample communications among returnees is very important. All returnees from Iran were placed in the same wing of the hospital. Between their physical, psychiatric, and dental examinations, returnees mingled in common areas, passed on information of importance to the group, and shared personal experiences. Many former hostages did not possess a full knowledge of the experiences of other captives until these exchanges.

Stage IV – Denial

The fourth stage lasts from days to weeks. After medical examinations and debriefings and a few days of rest and recuperation, released captives should begin to meet the press. This is a time that many make personal statements regarding their captivity experiences. However, one question the press asks repeatedly is: "What kinds of problems are you now having due to the stresses of your captivity?" Returnees might answer this question quite candidly on their first day or two after release, but as they begin the denial stage their answer will be: "The doctors may think that something bad may happen, but I know that I will be perfectly okay." There is a readiness of the public to believe such answers because such statements reinforce a hero image of the former captives. Such statements, however, frequently omit significant physical and/or psychological difficulties and should not be taken at face value.

It is important for health-care providers not to be taken in by such denial but also not to vigorously challenge it. Gentle reminders to continue with periodic follow-ups should be given and lines of communication should be kept open. Later, the ex-captives' possible entry into treatment, if needed, can be proposed. Often working with family members is also important at this point.

Denial also presents problems such as impulsive actions on returning home. Ex-captives are sometimes prone to buying expensive cars or investing savings accrued during captivity in poorly conceived financial schemes. Many entrepreneurs will try to use the ex-captives' notoriety to support their own enterprises.

Stage V – Restitution

The fifth stage lasts from weeks to months. Efforts toward making restitution are an interesting psychological phenomenon. The area of food is a good example. Due to generally severe and prolonged nutritional deprivation, most hostages return with a lean body mass that, combined with the plentiful exercise during captivity, renders them extremely fit. Some weight gain over the first few months home should be expected. However, moderate to gross obesity was seen in several of the returned hostages from Iran just a few months after their release. When questioned about how they had gained so much weight in such a short time, the typical answer was: "I just felt that when tempted I couldn't deny myself."

A second area of restitution occurs in readjustments among family members. Long-term captivity,

especially with extended periods of social isolation, appears to have the greatest impact. Captives' emotional and intellectual functions may have become dulled from the monotony of prison life. Table manners and bathroom and sleeping habits acquired in captivity may be unacceptably crude in the home situation. Further, family members may have become accustomed to managing their daily lives by themselves and resist direction from the ex-captive. Ex-captives may try to reestablish the family structure and function that existed before their capture and find that they are not wanted. Former captives may also try to provide, over a very short period of time, all the love and attention that they were prevented from giving family members during captivity.

A third problem area is when ex-captives return to work. Employers are frequently tempted to offer long vacations to returnees, but the returnees themselves generally wish to resume work as soon as possible. This is frequently due to a need to reaffirm their previous skills and demonstrate their worth to their organizations. In some cases, particularly those involving people held in long-term captivity, job refresher courses and even retraining are necessary. In the instances of the returned military ex-hostages held along with U.S. Embassy officials in Iran, most were given 3 months of vacation in addition to their first 2 weeks of medical treatment and official receptions. This prolonged vacation period led to problems for several men in terms of how to use this time profitably. The long time away from the military also contributed to the decision by some of the men to resign from the military and switch to other occupations that had been offered to them on their return home.

In addition, family and friends should be advised to limit recitals of the ex-captives' experiences during the first days to weeks after their return. Such early recitals can recreate suffering. In contrast, weeks to months later, giving lectures and speeches on their captivity experience can be therapeutic for releasees. If ex-captives have a talent for writing, the preparation of an article or book about their experiences may help them in working through their captivity experiences.

Stage VI – Gradual Readjustment

The sixth stage lasts from months to years. If the criteria for readjustment from captivity stress simply included whether former captives returned to work or whether their marriages remained intact, the majority would be declared as recovered. If the criterion for recovery is freedom from the psychological scars of captivity, complete recovery may never occur.

Life-long anxieties and depression have been seen in victims of especially severe captivity stress, such as Nazi concentration camp survivors. Hardly a day goes by that they do not suffer distressing psychiatric symptoms emanating from their Holocaust experiences.

Illnesses that develop following ex-captives' return are often an indicative of incomplete recovery. In follow-up studies of American POWs from Korea, as well as from Asian POW camps in World War II (where torture and nutritional deprivation were extremely severe), returned POWs showed significantly increased illness rates for infectious, cardiovascular, degenerative, and psychiatric disorders for the next 25–30 years. Even accidental deaths were higher for returned captives than for controls during this time. In contrast, when U.S. Navy aviators returned from prisoner-of-war captivity during the Vietnam War were similarly studied, the elevated illness rates for physical and psychological illness returned to control-group levels 8 years following their return. Thus, even with the best outcome, these studies point to an enduring effect of severe and prolonged captivity on physical and psychological health.

Some returnees do better than others in terms of illness during their subsequent years of life. How can medical personnel learn to correctly identify people who will probably do well versus those who will probably have multiple problems? The answer is: carry out an illness assessment 1 year after return. When 133 Navy returned prisoners of war from Vietnam were seen after their first year of return, they fell into two groups: The first group, comprising 96 men, reported good health over the previous year; the second group, comprising 37 men, reported significant psychiatric illnesses. The most prevalent psychiatric illnesses were substance abuse and adjustment reaction. As shown in [Figure 1](#), more than two-thirds of men who were healthy at follow-up year 1 stayed healthy during follow-up years 2–5. Of the group (30 men) that reported illnesses during years 2–5, 63% of the illnesses were minor in severity (e.g., mild anxiety disorder). In contrast, of the group that was ill in year 1, more than three-quarters continued to report significant illnesses in years 2–5 ([Figure 2](#)). Further, 59% of these reported illnesses were of major significance (e.g., major depressive disorder).

Although the sample is smaller, this same phenomenon was observed in the Americans held hostage in Iran. As [Figure 3](#) shows, 21 of the 35 former hostages studied reported good health during the first follow-up year. Of this healthy group, two-thirds remained healthy during the years 2–5. Of the group who were ill during years 2–5, 86% reported that these illnesses were minor in severity. In contrast, in the

Figure 1 More than two-thirds of former prisoners of war (returned Navy Vietnam POWs; $N = 133$) who were healthy 1 year after release were also healthy 5 years after release. Sixty-three percent of those who were ill at the fifth follow-up year reported illnesses minor in severity.

Figure 2 More than three-quarters of former prisoners of war (returned Navy Vietnam POWs; $N = 133$) who were ill 1 year after release were also in ill health 5 years after release. Fifty-nine percent of those who were ill at the fifth follow-up year reported illnesses of major severity.

Figure 3 Two-thirds of former American hostages held in Iran ($N = 35$) who were healthy 1 year after release were also healthy 5 years after release. Eighty-six percent of those who were ill at the fifth follow-up year reported illnesses minor in severity.

Figure 4 More than 70% of former American hostages held in Iran ($N = 35$) who were ill 1 year after release were also in ill health 5 years after release. Sixty percent of those who were ill at the fifth follow-up year reported illnesses of major severity.

group (14 men) that was initially ill, more than 70% remained ill during years 2–5 (Figure 4). In addition, 60% of the illnesses reported were major in severity.

Comment

The chances to study returned captives from stressful incarcerations, such as prisoners of war or political hostages, are rare. The military and in the U.S. Department of Veterans Affairs have conducted the bulk of such investigations. Follow-up studies of World War II POWs liberated from Japan, POWs returned from the Korean War, and former U.S. Navy POWs held in North Vietnam have spanned 20 years or more. A recent report assessing psychiatric illnesses in the Navy POW group found a 20-year prevalence rate of just 10%. In this day of labeling vast numbers of military stress survivors as having posttraumatic stress disorder (PTSD), the long-term psychological health of this Navy group of severely stressed individuals is truly remarkable.

Part of the answer to the long-term health of these Navy POWs is that they were a group of highly intelligent and talented aviators. Throughout their lives, these individuals had responded to challenges in their lives with success. Many then saw the challenges of surviving being prisoners of war as yet another life challenge that they would overcome. And most of them did so. Such individuals serve as an inspiration to all of us by their indomitable spirit in the face of enormous adversity.

Baroreflexes and Blood Pressure Regulation

Human Studies of Cardiovascular Responses to Mental Stress

Pathophysiological Aspects

Glossary

Epinephrine (EPI)

The hormonal link of the sympatho-adrenal system; epinephrine is released into the bloodstream from the adrenal glands.

Norepinephrine

The principal neurotransmitter (chemical signaling substance) released from the sympathetic nerves. A neurotransmitter acts locally where it is released. Dream sleep.

Rapid eye movement (REM) sleep Receptors

Molecular structures that carry messages into cells from biological substances (e.g., neurotransmitters and hormones) outside of the cells that they influence. Sympathetic receptors are also termed adrenoceptors.

Renin-angiotensin system

Renin is released from the kidney and regulates the formation of angiotensin II, which is a potent vasoconstrictor and has many other functions. β -Adrenoceptor stimulation increases renin release.

Stroke volume

The volume of blood pumped into the vascular system by one heart beat.

Sympathetic neuroeffector mechanisms

The regulation of sympathetic nerve function (i.e., nerve activity), the release of norepinephrine, and its effects on the cells that it influences via the stimulation of specific receptors (α - or β -adrenoceptors).

<i>Sympathetic system</i>	One of the two classic autonomic systems of nerves that regulate bodily functions. Sympathetic nerves to the heart increase heart rate and contractility via β -adrenoceptor stimulation by norepinephrine, whereas the parasympathetic vagal nerve slows the heart rate via release of its neurotransmitter acetylcholine.
<i>Tachycardia</i>	A rapid heart rate.
<i>Thrombosis</i>	Blood clotting that blocks the flow of blood.
<i>Vasoconstriction</i>	The narrowing of a blood vessel to decrease blood flow.
<i>Vasodilatation</i>	The widening of a blood vessel to increase blood flow.

Background

The cardiovascular system adapts to stress by changes that, from a teleological perspective, are meant to improve the chances of survival when the organism is threatened. The response pattern has been called the defense reaction and serves, in its simplest form, to prepare the organism for fight or flight. Animal experiments by Hilton, Folkow, and others have established a typical pattern of cardiovascular responses to stress, which may be elicited by the electrical stimulation of certain regions of the brain as well as by environmental stimuli in awake animals. The defense reaction involves elevations of cardiac output and blood pressure and a redirection of blood flow from the kidneys and splanchnic organs to skeletal muscle. A similar response pattern is elicited by mental stress in humans. The short-term survival benefits of the changes associated with the defense reaction may not be paralleled by beneficial consequences in the long term, when elicited repeatedly in individuals living in an urban society with everyday stresses.

Research on the importance of psychosocial factors and stress in cardiovascular disease has been rather intense. There is consensus that stress is of importance, but its exact role in cardiovascular pathophysiology has been somewhat illusive for many reasons: what is stress? how do positive and negative stressors differ? how can stress be quantitated? is laboratory stress testing relevant for the everyday situation? and how do personality factors influence cardiovascular responses to stress and for consequences of these responses? Despite this complexity, it is clear that stress (in terms of stimuli that influence the cardiovascular system in a certain direction) is involved in cardiovascular disease and its consequences. This presentation focuses on the effects of mental stress on the cardiovascular system and the mechanisms probably involved, with a few comparisons with the effects of physical exercise and other stressors.

Historical Perspective

From a cardiovascular point of view, it is pertinent to mention the work of Walter B. Cannon, who, in the first decades of the twentieth century, studied the responses of animals to stress. He described the fight-or-flight reaction and a homeostatic theory of how organisms adapt to threatening environmental influences. Cannon recognized the importance of the sympathetic system and proposed that the adrenal glands secreted sympathin, which mediated the responses to stress. However, von Euler could later show that sympathetic nerves use the neurotransmitter norepinephrine, whereas the circulating hormone secreted by the adrenal glands was a related substance, epinephrine. Later, adrenocorticotrophic hormone (ACTH) and glucocorticoids secreted from the adrenal cortex were added to the list of stress hormones. Goldstein reviewed the homeostatic mechanisms in relation to research on stress and distress from Darwin and Bernard to 1995. He noted the lack of a unifying concept of stress and that this reflects the complexity with which the organism may respond to stress due to feedback regulation and the multiplicity of systems involved in the control of homeostasis.

Methodological Comments

In cardiovascular stress research, the conditions for resting measurements are most important because any expression of cardiovascular reactivity to stress depends on the basal value with which the stress value is compared. In fact, the basality of resting measurements (as reflected by, e.g., heart rate and plasma epinephrine levels) may be the most important determinant of study results. The stress test used should, of course, be standardized when comparing stress reactivity in individuals or between groups. Responses should be of sufficient amplitude to allow the discrimination between different conditions and be reasonably reproducible. Many factors, including personality factors, modulate the perception of stress and the degree of arousal caused by the stressor, as well as cardiovascular responses elicited by it (Figure 1).

What Is a Relevant Stressor?

For a cardiologist, stress testing means evaluating whether myocardial ischemia can be provoked by a stimulus that increases myocardial oxygen demand, such as physical exercise. However, mental stress may also provoke ischemia. Any increase in mental activity – even quiet speaking and REM periods (dreaming) during sleep – evokes cardiovascular changes. In fact, REM sleep may even precipitate

Figure 1 Stimulus–response scheme for cardiovascular responses to psychological stress. The perception of stress is modified by multiple factors, which reinforce or attenuate the arousal evoked by the stimulus. The cardiovascular response is mediated by neurohormonal activation. Several factors may modify the neurohormonal activation, as well as responses to the mediating neurohormones. Finally, the cardiovascular responses may be buffered by baroreflexes aiming at maintaining blood pressure at prestimulus levels, but the efficiency of the baroreflex is attenuated during stress. CNS, central nervous system.

myocardial infarction. Interviews on sensitive personal issues may be most relevant when studying the cardiovascular risks of stress, but they cannot be standardized for comparing individuals or groups. The question is whether laboratory stress tests mimic responses elicited by mental stimuli normally encountered. Herd used an operational definition of relevant stressors whereby “a psychological stressor is one that causes a predictable stress response in a predictable percentage of index subjects” and went on to define the cardiovascular stress response as changes seen in the defense reaction (1991). Various standardized stress tests have been developed that fit this definition.

Among the most common mental stress tests for cardiovascular research are mental arithmetic (MA)

and Stroop’s color word conflict test (CWT). Tests may also be based on auditory feedback or video games. MA is simple to administer, but the test results are influenced by the speed of the test and by the (variable?) harassment of the subject; individuals may also have very different abilities for coping with mathematics. MA produces substantial responses in some studies (e.g., those of Brod and coworkers), but weak responses in other studies. CWT is administered in different ways, and the magnitudes of responses depend on the version used (how color words are presented, how responses are made, and whether there is auditory interference). We have used MA (in various versions, with or without external pacing) and CWT in a modification with auditory interference developed by Frankenhaeuser in the 1960s and have found the latter to be particularly useful.

Adaptation to the same stressor occurs on repeated administration, whereas responses to a novel stressor are either intact or enhanced. Such adaptation involves information processing (coping, etc.) rather than the desensitization of the target organs. Animal experiments suggest that chronic stress can even result in enhanced responses to a novel stressor due to increased synthesis, storage, and release of neurotransmitters.

In clinical research, it may be difficult to find newly diagnosed patients who have not received any treatment. When drug treatment is discontinued, the researcher should minimize carryover effects or rebound phenomena by allowing sufficient time for the treatment effects to disappear. For example, diuretics may have long-lasting effects on sodium and fluid balance, and the withdrawal of a β -blocker may lead to rebound phenomena with increased β -adrenoceptor sensitivity. Such aftereffects may persist longer than is appreciated by many authors and should be taken into account.

Neurohormonal Mechanisms

Before describing the cardiovascular responses to mental stress, I briefly comment on the neurohormonal systems that may be involved and that are discussed in relation to these responses. In general, neurogenic control is suited for fine-tuned influences on individual organs or cells, whereas hormonal influences are diffuse.

The Sympathoadrenal System

The sympathoadrenal system is involved in short-term (phasic) responses to stress. Epinephrine (adrenaline), which is often considered to be *the* stress hormone, is secreted during stress, and epinephrine

levels in plasma or urine reflect the degree of arousal experienced.

The sympathetic nerves may operate in a differentiated fashion, with varying levels of activity and varying responses to stress in different organs. Muscle sympathetic nerve activity during stress may even differ in different parts of the body. Thus, the common term sympathetic tone, which indicates synchronized activity throughout the body, is not appropriate. If possible, sympathetic activity should be studied locally, in the organ of interest.

Norepinephrine is the principal neurotransmitter of sympathetic nerves, although the cotransmitter neuropeptide Y may contribute to vasoconstrictor responses when sympathetic nerves fire at high frequencies. Norepinephrine stimulates α - and β -adrenoceptors. Catecholamines are rapidly cleared from plasma, with half-lives of 1–2 min, but the effect of a sympathetic nerve impulse is much shorter than that, due to local inactivating mechanisms such as the reuptake of norepinephrine into the nerve. Norepinephrine may also function as a circulating hormone when the plasma levels of norepinephrine are markedly elevated, such as during physical exercise. Resting levels of norepinephrine in plasma are $\approx 1 \text{ nmol l}^{-1}$, and threshold levels for hormonal effects are 3–4 nmol l^{-1} . Sympathetic nerve activity may be monitored in humans by:

- Direct recordings of impulse activity in nerves supplying skeletal muscle and skin but not in organs of perhaps greater interest in the context of mental stress.
- Analyses of heart rate variability (for cardiac sympathetic activity).
- Measurements of norepinephrine levels in plasma and norepinephrine release from various organs. Measurements of norepinephrine release and spill-over into plasma can be refined by the use of an isotope dilution method involving infusions of radiolabeled norepinephrine, which was developed by Esler and coworkers.

These techniques all have their technical difficulties and limitations. They complement one another because the release of norepinephrine from the sympathetic nerves is influenced by prejunctional regulation (i.e., variable release per nerve impulse) and the sensitivity of the receptors involved may vary when measuring functional responses, such as heart rate.

Epinephrine may, as a circulating hormone, stimulate α - and β -adrenoceptors in all organs. Under certain circumstances, epinephrine can be taken up into and re-released from sympathetic nerves in such quantities that a role as a co-transmitter is possible, but this is normally not important. Thus, epinephrine

is the classic hormonal link of the sympathoadrenal system.

There is functional differentiation of sympathetic neuroeffector mechanisms; β_1 -adrenoceptors appear to be innervated receptors, and β_2 -adrenoceptors appear to be noninnervated or humoral receptors. This leads to epinephrine being functionally β_2 -selective at physiological concentrations in blood plasma (even though it is also an effective β_1 -agonist in *in vitro* systems) and provides a possibility of studying the importance of epinephrine for physiological responses to stress by examining the β -adrenoceptor subtype involved in the response. Similarly, α_1 -adrenoceptors appear to be innervated and α_2 -adrenoceptors non-innervated in the cardiovascular system, which has therapeutic implications and allows the separation of neurogenic and humoral influences.

Cholinergic Mechanisms

The heart is under dual autonomic control, with excitatory sympathetic nerves (stimulating β_1 -adrenoceptors) and inhibitory vagal nerves (releasing acetylcholine and stimulating muscarinic receptors). Acetylcholine is very rapidly inactivated after its release, allowing beat-to-beat control of the heart rate. The intrinsic rate of the sinus node is ≈ 90 –100 beats/min. Thus, the resting heart rate (usually 60–80 beats/min) is controlled to a large extent by vagal activity. Increased physical fitness reduces the resting heart rate by increasing vagal activity. Stress may thus increase heart rate by activating sympathetic nerves and/or by inhibiting the parasympathetic vagus nerve.

Animal research on vasodilator responses in skeletal muscle has demonstrated sympathetic vasodilator nerves that release acetylcholine. Work by Hilton suggested that such vasodilator nerves did not exist in primates, but early studies in humans suggested that it indeed was possible to elicit cholinergic vasodilation in the forearm with certain stressors. However, the literature on cholinergic vasodilation in human skeletal muscle is divided, and it cannot be definitely stated that this mechanism is of importance or under which conditions it may contribute.

Other Mediators and Mechanisms

The renin–angiotensin system may be activated by stress. Renin release from the kidney is under the influence of several factors, one of which is sympathetic nerve activity and β_1 -adrenoceptor stimulation. Salt deprivation increases renin secretion, and salt loading decreases it. Renin catalyzes the formation of angiotensin II, which is a potent vasoconstrictor peptide with several other biological actions, including the enhancement of aldosterone secretion. Thus, the system is salt-conserving. The relative importance

of angiotensin II and norepinephrine as mediators of vasoconstriction during stress may vary. High sodium intake tends to enhance cardiovascular responses to mental stress, but this is most likely independent of the renin–angiotensin system, which should be downregulated under such conditions.

There are several neuropeptides (e.g., neuropeptide Y and calcitonin gene-related peptide), and other peptides (e.g., atrial natriuretic factor and endothelin) that may be involved in cardiovascular responses to stress. Their roles during stress have not been sufficiently elucidated, in part due to the lack of good antagonists for human use.

Platelets store serotonin (5-hydroxytryptamine), which is released when the cells are activated, and activated platelets synthesize thromboxane A₂. Both of these substances may stimulate platelets (positive feedback) and cause vasoconstriction, especially when the vascular endothelium is not functioning normally. Stress may activate platelets.

Flow-mediated vasodilatation has been recognized for a long time. Furchgott showed the importance of endothelial cells for vasodilator responses and proposed the existence of an endothelium-derived relaxing factor (EDRF). Nitric oxide (NO) was shown by others to be an important component, if not the only EDRF. NO released from the vascular endothelium serves both as a vasodilator and an inhibitor of platelet adhesion and aggregation, and the inhibition of NO synthesis or defective NO production by the endothelial cells may increase vascular tone and the risk of thrombosis. NO appears to be a rather ubiquitous substance in the body, which may be involved in neurogenic mechanisms and influence cardiac function as well. However, the importance of this for stress responses of the cardiovascular system is unknown. Flow-mediated vasodilatation (i.e., NO) is probably important for vasodilator responses to stress in some organs.

Baroreflexes and Blood Pressure Regulation

The cardiovascular system is regulated in a complex manner, with compensatory adjustments when changes are elicited by various stimuli. Normally this fine-tuned system strives to maintain a certain blood pressure (which may be either normal or high, if the individual has hypertension) via arterial baroreflexes, which serve to dampen the change. If the blood pressure rises, there is a reflexogenic inhibition of the heart and reduced vasoconstrictor nerve activity; conversely, if the blood pressure decreases there is a reflexogenic stimulation of the heart with increases in heart rate and cardiac output and a compensatory

increase in vasoconstrictor nerve activity. If cardiac output is lowered (e.g., by drug treatment), peripheral blood flow will decrease to maintain the blood pressure. In the long term, baroreflexes are reset to the new blood pressure level if, for example, a patient with hypertension is treated with a blood pressure lowering drug.

There are also receptors that sense venous pressure and participate in volume regulation. If venous pressure decreases, reflexogenic and hormonal changes occur that serve to conserve salt and water (i.e., renal responses) and to maintain blood pressure by increasing venous tone and reducing peripheral blood flow. The kidney is intimately involved in the regulation of blood pressure according to the Guyton's classic theory of cardiovascular homeostasis. However, there are also indications that blood pressure is a regulated variable and that neurogenic mechanisms are important for both short- and long-term levels of blood pressure.

During stress, the influence of baroreflex regulation of the circulation diminishes, and centrally elicited pressor mechanisms may operate under less influence of reflexogenic modulation than if blood pressure is increased by other maneuvers (Figure 1). As discussed by Julius, there seems to be some blood pressure-sensing mechanism that regulates the blood pressure during stress because interference with one pressor mechanism often leads to another one taking over and the pressor response to the stimulus remaining intact.

Human Studies of Cardiovascular Responses to Mental Stress

Figure 2 illustrates schematically how mental stress elevates blood pressure in humans, based on results from a number of studies. Pressor responses to mental stress generally depend on the increase in cardiac output because systemic vascular resistance decreases. In an early series of investigations, Brod and coworkers studied the cardiovascular responses to mental stress, mainly forced MA (using procedures creating substantial hemodynamic responses), in normotensive and hypertensive subjects. An example is given in Figure 3, which shows that arousal caused by the suggestion of exercise elicited responses that were qualitatively similar to those from mental arithmetic. A few examples of responses to CWT, from our work, are mentioned next.

Cardiac Responses

The increase in cardiac output is caused mainly by an increase in heart rate, but an increase in stroke volume also contributes (Figure 2). Tachycardia may

Figure 2 Schematic representation of the cardiovascular response pattern of the defense reaction. The pressor response is mainly cardiac output-dependent, and the increase in cardiac output depends mainly on an increase in heart rate. The vascular response is a net reduction of systemic vascular resistance, but responses of individual organs vary considerably. ACTH, cortisol, and epinephrine are markers of the arousal evoked by the stressor. Established and possible mediators of the cardiovascular responses are indicated. ACTH, adrenocorticotropic hormone; CNS, central nervous system. Modified from Hjelmahl, P. (1993), Plasma catecholamines – analytical challenges and physiological limitations, *Baillière's Clinical Endocrinology and Metabolism* 7, 307–353.

be elicited by both increased sympathetic nerve activity and vagal withdrawal. Increases in stroke volume are related to increased contractility (which can be demonstrated by, e.g., echocardiography), as well as an increase in venous return, which supports the filling of the heart in diastole. Thus, work by Brod and coworkers has demonstrated that stress causes venoconstriction, which results in the centralization of the blood volume and supports cardiac filling. Studies with pacing alone showed that an isolated increase in heart rate does not efficiently elevate cardiac output – an increase in contractility and an adequate distension of the heart in diastole contribute to the stress response.

The effects of β -blockade by metoprolol (β_1 -selective) or propranolol (nonselective) on some invasive hemodynamic variables are illustrated in [Figure 4](#). Healthy volunteers were subjected to CWT (the Frankenhaeuser version), which was found to elicit clear-cut and rather reproducible (see control group) responses. The two β -blockers inhibited the heart rate response similarly, indicating that the sympathetic component was β_1 -mediated (neurogenic). The vagal component in the tachycardia elicited by mental stress is reflected in the persisting, although blunted, tachycardia seen after β -blockade in sufficient doses to eliminate the increase in stroke volume during stress ([Figure 4](#)). The stroke volume response

Figure 3 Comparison of general and regional hemodynamic responses to mental arithmetic stress and suggestion of heavy muscular exercise in a healthy subject from the studies of Brod and coworkers. Mental stress and the anticipation of physical stress elicited similar cardiovascular responses, both of which resemble the defense reaction. Illustrated are cardiac output (CO), systemic vascular resistance (TPR), blood pressure (BP), skin temperature, renal paraaminohippurate clearance (C_{PAH}), renal vascular resistance (RR), extrarenal vascular resistance (ERR), forearm vascular resistance, and forearm blood flow. From Brod, J. (1963), Haemodynamic basis of acute pressor reactions and hypertension, *British Heart Journal* **25**, 227–245, with permission from the BMJ Publishing Group.

Figure 4 Cardiac and systemic vascular responses to mental stress induced by Stroop's color word conflict test (CWT; the Frankenhaeuser version) in healthy male volunteers. a, Cardiac output (measured by thermodilution); b, stroke volume; c, heart rate; d, systemic vascular resistance. Thirty subjects were divided into three groups, in which CWT (stress) was repeated without treatment (control) or after intravenous injection of the β_1 -blocker metoprolol or the nonselective β -blocker propranolol. The mean arterial pressure response to stress (≈ 20 mmHg) was little affected by the treatments given. PRU, peripheral resistance units. From Freyschuss et al. (1988), *American Journal of Physiology* 255, H443–H451, with permission from the American Physiological Society.

was attenuated by metoprolol and abolished by propranolol, suggesting contributions of both neurogenic (norepinephrine) and hormonal (epinephrine) effects. However, stroke volume is also sensitive to afterload, and the effects of β -blockade on systemic vascular resistance may have influenced the stroke volume response to stress.

The coronary circulation is to a large extent regulated by cardiac metabolism, and it is difficult to separate β -adrenoceptor-mediated coronary vasodilation from that induced by increased cardiac metabolism and flow-mediated vasodilation. However, α -adrenergic coronary vasoconstriction may occur when the endothelium is dysfunctional or when cardiac metabolism is inhibited.

Peripheral Vascular Responses

The decrease in systemic vascular resistance during mental stress is related to vasodilation in skeletal muscle and adipose tissue, whereas there is vasoconstriction in the kidneys, splanchnic organs, and skin (Figure 2). The experiment of Brod and coworkers (Figure 3) illustrates marked vasodilation in the forearm simultaneously with reduced renal clearance of para-aminohippurate (i.e., renal vasoconstriction) and a decrease in skin temperature (i.e., vasoconstriction in skin); other experiments have shown splanchnic vasoconstriction.

Limb blood flow The decrease in systemic vascular resistance in the experiments illustrated in Figure 4 was attenuated by β_1 -blockade and abolished by propranolol. These effects of β -blockade may reflect blockade of vascular β -adrenoceptors (which are of the β_2 subtype) and/or peripheral vascular adaptation to the effects of β -blockade on the cardiac response to stress. The increase in blood pressure during mental stress was little influenced by β -blockade (data not shown), which is in agreement with the results of several other studies. If, as discussed by Julius, blood pressure is the primarily regulated variable, the attenuation of the increase in cardiac output results in compensatory changes in vascular responses in order to achieve the same level of blood pressure during stress as would be obtained without such attenuation. Vasodilator responses are then secondary to, and governed by, cardiac responses. Further support for this idea was obtained in studies of systemic NO synthesis inhibition, which increased vascular resistance and blood pressure at rest but did not influence the blood pressure level achieved during stress.

These experiments included measurements of calf blood flow (by plethysmography) and of adipose tissue and skeletal muscle blood flow (by isotope

Figure 5 Peripheral vascular responses to mental stress (Stroop's color word conflict test, CWT) in the experiments illustrated in Figure 4. a, Adipose tissue; b, skeletal muscle; c, calf. CWT elicited similar vasodilation in adipose tissue of the abdomen (similar responses were found in adipose tissue on the thigh), skeletal muscle (gastrocnemius muscle), and the calf. Tissue blood flows were determined by the local clearance of ^{133}Xe ; and calf blood flow was measured by venous occlusion plethysmography. PRU, peripheral resistance units. From Linde et al. (1989), *American Journal of Physiology* 256, E12–E18, with permission from the American Physiological Society.

clearance methods). Figure 5 shows similar vasodilation in adipose tissue, skeletal muscle (the gastrocnemius muscle) and the entire calf in response to CWT. β -Blockade inhibited these local vasodilator responses similarly, as previously shown for systemic vascular resistance. In other studies, even greater vasodilator responses than those seen in the leg were found in the human forearm with the same stress test (Figure 6). Of interest are findings by Rusch and coworkers that blood flow responses of the arm and leg

Figure 6 Forearm vascular responses to Stroop's color word conflict test (CWT) and to intravenous (IV) and intra-arterial (IA) infusions of epinephrine (EPI), in relation to epinephrine concentrations before and during interventions. CWT elicited a marked forearm vasodilator response with a small increase in venous plasma epinephrine. Responses to IA epinephrine were greater than those to IV epinephrine, suggesting reflexogenic buffering of the forearm vasodilator response to systemic epinephrine. Interpolation of vasodilator responses to the epinephrine concentration achieved by the same individual during CWT showed that epinephrine may have contributed 10–30% of the vasodilator response to stress. From Lindqvist et al. (1996), *American Journal of Physiology* 270, E393–E399, with permission from the American Physiological Society.

to different stimuli (including MA) differed and that vasodilatation was more prominent in the arm than in the leg. Others have found that differences in the baroreceptor mediated the control of limb blood flow in the leg and the forearm. Recordings of muscle sympathetic nerve activity by Anderson and co-workers showed that MA increased muscle sympathetic activity in the leg but not in the arm, when they were simultaneously recorded (Figure 7). Thus, the sympathetic response to mental stress is so differentiated that differences in muscle sympathetic nerve activity can be seen even between the upper and lower limbs. Increases in muscle sympathetic nerve activity may serve to buffer the vasodilator response to stress.

NO release and flow-mediated vasodilatation may be involved in the blood flow response of skeletal muscle to mental stress. Other possible mediators are acetylcholine (although we found no neurogenic component in the sustained forearm vasodilator response to CWT), vasodilating peptides, and epinephrine. Of interest is that the forearm vasodilator response to CWT (a 50% decrease of local vascular resistance) was not altered by systemic NO synthesis

inhibition, even though previous studies had shown attenuation of stress-induced forearm vasodilatation with local inhibition of NO synthesis. Thus, systemic (centrally mediated?) influences on muscle blood flow may override locally acting influences by, for example, NO released from the endothelium.

Thus, it is well established from work by several groups and with several different stress tests that limb blood flow increases due to vasodilatation in the skeletal muscle and adipose tissue, whereas there is vasoconstriction in the skin. Interestingly, skeletal muscle vasodilatation appears to differ in different regions of the body. The mechanisms involved are not entirely clear.

Renal blood flow The kidneys, which receive $\approx 20\%$ of the cardiac output, are important in the regulation of blood pressure – both in the short term, and in the long term – and appear to be a target for stress effects. Several groups have shown renal vasoconstriction, renin release, and/or altered renal function in response to mental stress. Examples are shown in Figure 3 for the work of Brod and co-workers and in Table 1 for our work. Of particular interest is that renal vascular responses to mental stress may be enhanced in hypertension. Thus, Hollenberg and coworkers found that very mild stress induced by a nonverbal IQ test (which did not increase blood pressure) elicited clear-cut renal vasoconstriction among hypertensives but not among normotensives without a family history of hypertension; those with a family history of hypertension had an intermediate response. Renin release was similarly differentiated among individuals in the Hollenberg study.

Tidgren and coworkers performed a series of investigations of renal vascular responses to different stimuli, based on a renal venous thermodilution technique that allowed rapid measurements of renal blood flow. Table 1 lists some of these results. It may be seen that mental stress (CWT) increased renal vascular resistance by 50% and increased the renal overflows of renin and norepinephrine markedly. Isometric handgrip exercise was less efficient, especially regarding renin release, despite a similar increase in mean arterial pressure (approximately 20 mmHg with both stimuli). The renal vasoconstrictor response to mental stress was similar to that elicited by dynamic exercise of moderate intensity (60% of maximum effort). Heart rate and arterial plasma epinephrine increased more with CWT than with isometric handgrip, whereas dynamic exercise increased heart rate still more, with a smaller increase in epinephrine at a similar level of renal vasoconstriction. Thus, the patterns of responses differ among these three stimuli. The renal vasoconstrictor

Figure 7 Simultaneously recorded activity in the arm and leg in healthy individuals during mental arithmetic. a, Integrated muscle sympathetic nerve activity (MSNA); b, MSNA (bursts/100 heart beats); c, heart rate; d, blood pressure. MSNA increased in the leg but not in the arm in response to mental stress, indicating that skeletal muscle blood flow is under different neurogenic modulation in different regions of the body during stress.

DBP, diastolic blood pressure; MBP, mean blood pressure; SBP, systolic blood pressure;

and renin responses to mental stress were correlated to the renal norepinephrine overflow response (i.e., sympathetic nerve activity). The possible importance of epinephrine is discussed next.

Animal studies by di Bona, Koepke, Thorén and others have shown that renal vasoconstriction, as well as decreases in renal sodium excretion and increases in renin release, elicited by mental stress are sympathetically mediated and that these responses are enhanced in spontaneously hypertensive animals. Thus, the sympathetic nerves are important for renal responses to stress. Work in humans is less extensive, but the results discussed here tend to support the conclusion that the kidney is a target organ for stress and that sympathetic nerve activity is involved.

Is Epinephrine an Important Stress Hormone?

When given intravenously, epinephrine increases cardiac output mainly by increasing stroke volume. This is perceived as tachycardia (or the heart is pumping harder), even though the heart rate is relatively little influenced unless the dosage of epinephrine is high. The increase in stroke volume is related to an increase in cardiac contractility as well as a reduction

of afterload due to the systemic vasodilatation elicited by epinephrine. During stress, however, the increase in cardiac output is mainly related to an increase in heart rate, due to increased cardiac sympathetic nerve activity and vagal withdrawal. Even though the human heart is endowed with epinephrine sensitive β_2 -adrenoceptors, the cardiac response to stress is thus mainly neurogenic.

Epinephrine is a potent vasodilator when infused intravenously or intra-arterially. The vasodilator response is elicited by β_2 -adrenoceptor stimulation, and the α agonistic effects of epinephrine become apparent only after blockade of vascular β_2 -adrenoceptors or at supraphysiological concentrations of epinephrine. In the absence of β -blockade, intravenously infused epinephrine does not change mean arterial pressure within the physiological range, but concentration-dependent decreases in diastolic blood pressure (reflecting systemic vasodilatation) and increases in systolic blood pressure (reflecting increased stroke volume) are elicited. The importance of epinephrine for vascular responses to stress may be deduced from comparisons of the plasma concentrations achieved during stress and those required for physiological

responses, as well as by effects of β -blockade. **Figure 6** illustrates intraindividual comparisons of responses to CWT and infused epinephrine with regard to the forearm circulation; similar comparisons were made in our kidney studies.

Intravenously infused epinephrine may elicit reflexogenic increases in muscle sympathetic nerve activity. This is seen in **Figure 6**, which illustrates that epinephrine is more efficient when infused locally (intra-arterially) than intravenously. When vasodilator responses to CWT and epinephrine were compared, we found that epinephrine contributed to only a small extent (10–30%, on average). Data on local infusions of propranolol support this contention. Thus, epinephrine does not explain the vasodilation in human skeletal muscle during mental stress.

In the kidney study of mental stress (**Table 1**), there was no vasoconstrictor (or vasodilator) response to intravenously infused epinephrine, even at plasma concentrations as high as 6 nmol l^{-1} . Renal norepinephrine overflow was little influenced, but there was a concentration-dependent increase in renin release from the kidney. Epinephrine might thus contribute slightly ($\approx 20\%$) to renin release but not to renal vasoconstriction during mental stress.

In summary, the cardiovascular responses to mental stress in humans cannot be explained by epinephrine, but this hormonal link of the sympathoadrenal system may contribute to certain responses. The conception that epinephrine is the stress hormone is not correct from a functional point of view. However, the epinephrine response to stress does reflect the stress perceived and the arousal of the individual, and it is a good marker for the stimulus intensity of a stressor.

Pathophysiological Aspects

Stress is considered to be involved in the pathogenesis of several cardiovascular disease states, and stress may provoke acute cardiovascular complications, such as myocardial infarction and sudden death in individuals with symptomatic or asymptomatic atherosclerosis. However, for reasons already discussed, it is difficult to define the exact role of stress in cardiovascular disease.

Animal studies have shown that repeated mild activation of the defense reaction (by stress or by electrical stimulation of certain brain regions) may contribute to the development of hypertension. In addition, animals and humans with a genetic predisposition for hypertension often show enhanced cardiovascular and neurogenic reactivity to stress. Animal studies have also shown that stress may accelerate the development of atherosclerosis, as illustrated by

elegant experiments by Clarkson, Kaplan, and Manuck in cynomolgus monkeys showing increased atherosclerosis and by Henry in mice. In humans, it has been more difficult to link stress to atherosclerosis, but there are indications that stress, anxiety, and personality factors are involved. Furthermore, biobehavioral modifications may alter the course of coronary artery disease. Metabolic disturbances, such as diabetes and the metabolic syndrome (a cluster of risk factors with disturbed glucose regulation and often hypertension), are increasingly being linked to atherosclerotic disease. It is of interest that stress may accelerate these processes via the activation of the hypothalamic-pituitary-adrenal axis and release of cortisol. Thus, stress may indeed be involved in the pathogenesis of atherosclerosis, in agreement with popular views on the subject.

Various everyday stresses may trigger serious cardiovascular events, such as myocardial infarction, stroke, and sudden death (due to arrhythmia or myocardial infarction). Work by Mittleman, Muller, Willich, and others has shown diurnal variation in the incidence of myocardial infarction and that physical or mental stress precedes myocardial infarction or sudden death more frequently than would be expected by chance.

Acute myocardial infarction involves thrombosis in the coronary arteries, which may be triggered by many factors, including stress. The hemodynamic changes associated with mental or physical stress increase the risk of atherosclerotic plaque rupture, which is a potent stimulus for local thrombus formation. The mechanisms involved in thrombosis are complex and involve platelets and the coagulation system, as well as factors that oppose coagulation and dissolve blood clots (fibrinolysis). Stress-induced platelet activation may lead to the release of vasoactive substances, which promote ischemia and thrombus formation. Platelet activation may be enhanced by endothelial dysfunction (reduced release of NO and prostacyclin), increased shear stress in an atherosclerotic vessel, and other platelet-activating effects of stress that operate also among healthy individuals. Endothelial dysfunction also promotes vasoconstrictor responses to stress in the coronary arteries and may contribute to imbalances between blood flow and metabolic demands (i.e., myocardial ischemia). Mental stress has indeed been shown to elicit abnormal coronary vasoconstriction and myocardial ischemia among patients with coronary artery disease. The ischemic myocardium is vulnerable to life-threatening arrhythmias, especially when sympathetic activity is increased and vagal activity is reduced, as is the case during stress. Thus, stress elicits cardiovascular and neurohormonal changes that are beneficial to the

healthy subject but detrimental to patients with coronary artery disease. In addition, stress produces prothrombotic alterations that may further increase the risk of myocardial infarction.

Alterations of the Function of the Stress System Leading
to the Development of Atherosclerosis and
Cardiovascular Disease

Glossary

Catecholamines Norepinephrine (norepinephrine), epinephrine (adrenaline), and dopamine are the mediators through which the autonomic nervous system responds to stressors and controls a wide variety of system functions, such as arousal, arterial blood pressure, glucose levels, etc.

Circadian rhythm Many functions of living creatures are subject to periodic or cyclic changes mainly influenced by the nervous system. These changes are intrinsic to the organism independent of the environment and are driven by a biologic “clock”. When they have a period of approximately 24 hours these rhythms are called circadian (around a day).

Cytokines Substances secreted from a number of different immune, including activated macrophages and lymphocytes, and nonimmune cells. According to their subtype they may exert a pro- or anti-inflammatory effect and activate the stress response.

Cushing’s syndrome The presence of symptoms and signs associated with prolonged exposure to inappropriately elevated levels of free plasma glucocorticoids.

Glucocorticoids The final endocrine effectors of the hypothalamic-pituitary-adrenal (HPA) axis. They are steroid pleiotropic hormones that exert their effects through ubiquitously distributed intracellular receptors. Glucocorticoids are crucial for the maintenance of resting and stress-related homeostasis, regulating and assuring the integrity of cardiovascular, metabolic, behavioral and immune homeostasis.

Metabolic syndrome A clustering of factors closely associated with the development of atherosclerotic cardiovascular disease. The most recent definition includes central obesity,

hypertriglyceridemia, low high-density lipoprotein (HDL) cholesterol levels, hypertension, and increased fasting glucose levels or diabetes mellitus type 2.

State of threatened or perceived threatened homeostasis. Stress can be of either physical, social and/or psychological origin. During stress, a coordinated adaptive response of the organism is activated that is crucial in achieving and maintaining homeostasis. If this response is excessive and prolonged or defective and inadequate, the organism is in dyshomeostasis, or allostasis (allo = different) or cacostasis (caco = bad). The main components of the adaptive response are the corticotropin-releasing hormone (CRH) and the locus-caeruleus-norepinephrine (LC-NE)/arousal and autonomic nervous systems and their peripheral effectors, HPA axis and the systemic and adrenomedullary limbs of the autonomic system.

Sympathetic nervous system The SNS along with the parasympathetic system consist the autonomic nervous system. The SNS is under direct control from the CNS, allowing rapid onset of actions of short duration either excitatory or inhibitory) as a result of the abbreviated half-lives of catecholamines.

Prevalence of Atherosclerosis – Cardiovascular Disease

Atherosclerotic lesions (atheroma) consist of asymmetric focal thickening of the innermost layer of the artery, the intima. Pathologic changes caused by atherosclerosis in the cardiovascular system, such as coronary heart disease, aneurisms of the aorta and brain, or peripheral limb ischemia, currently represent the most profound threat to the quality and expectancy of life in developed countries. It has been estimated that cardiovascular diseases (CVD) cause 38% of all deaths in North America and are the most common cause of death in European men under 65 years of age and the second most common cause in women. Ischemia of the myocardial and cerebral circulation – leading to myocardial infarction and stroke, respectively, develops when the atheromatous process prevents blood flow through the involved arteries either as a result of plaque rupture or endothelial erosion. Common risk factors for developing atherosclerosis are hyperlipidemia, hypertension, and

disorders of carbohydrate homeostasis, such as glucose intolerance and diabetes mellitus type 2 (DM2). The spectrum of these traditional risk factors has lately been incorporated under the entity of the metabolic syndrome, which also includes visceral obesity, insulin resistance, and/or blood hypercoagulation. Patients with the metabolic syndrome are at increased risk for developing atherosclerosis and, therefore, constitute a group for early intervention. Over the past two decades, there has been a striking increase in the number of people with the metabolic syndrome; this increase is associated with the global epidemic of obesity and DM2. There is an urgent need for strategies to prevent the emerging global epidemic of metabolic syndrome along with the elevated risk not only of DM2 but also of CVD.

Established and Evolving Risk Factors of Atherosclerosis

When traditional risk factors are taken into consideration, not all cases of CVD can be attributed to their presence. Studies, such as the Framingham Heart Study, have shown that approximately 50% of coronary heart disease cases can be explained by the three major cardiovascular risk factors – elevated serum cholesterol, hypertension, and smoking. In addition, although rigorous treatment of hypercholesterolemia and hypertension was expected to substantially decrease CVD, these diseases still remain the main cause of death globally and are expected to increase further owing to a rapidly increasing prevalence of obesity in developing countries and Eastern Europe and the continuing rise in the incidence of obesity and diabetes in the western world. To explain these observations, additional pathogenetic mechanisms have been thought to contribute, among which is the effect that chronic stress may exert in the development of the metabolic syndrome and the concurrent presence of systemic smoldering inflammation.

Common effector pathways appear to mediate the pathogenesis of metabolic syndrome, atherosclerosis and CVD. These include activation of the hypothalamic-pituitary-adrenal (HPA) axis, the systemic/adrenomedullary sympathetic nervous systems (LC-NE-SNS) and the inflammatory/immune response. These systems, either alone or in combination, can initiate and/or promote mechanisms related to the development of atherosclerosis, such as mobilization of low-density lipoprotein (LDL), which is manufactured and secreted into the circulation by the liver, as a carrier of cholesterol to peripheral tissues. Macrophages, a major component of the immune system, contribute to the vascular accumulation of cholesterol

by absorbing the oxidized forms of LDL and adhering to inflamed endothelium to ultimately form stenosis-causing plaques. Macrophages and the cytokines they produce can also be activated by the stress system, whereas cytokines are also a major link between obesity and endothelial dysfunction. Furthermore, alterations of cortisol secretion, effect, and dynamics have been thought to be related either directly and/or indirectly, through inhibition of systems that exert a protective effect, in the development of atherosclerotic lesions.

Alterations of the Function of the Stress System Leading to the Development of Atherosclerosis and Cardiovascular Disease

The Stress System

During stress, adaptive behavioral and peripheral responses are activated that optimize the ability of the organism to adjust homeostasis. Stress is associated with increased activity of the HPA axis and the LC-NE-SNS, which result in systemic elevations of their endocrine end-effectors, the glucocorticoids (cortisol) and the catecholamines (CAs). These compounds, together with other products of the stress system, such as for instance the cytokine interleukin (IL)-6, influence a variety of adaptive responses. The activation of the HPA axis is regulated by glucocorticoid negative-feedback control through glucocorticoid receptors (GR) in the central nervous system (CNS). Normally, there is a diurnal secretory pattern of cortisol with elevations in the early morning and decreases in the afternoon and evening hours. This basal activity is modified by stressful stimuli, which can be either physical (extreme environmental alteration, trauma, and toxins) and/or events that are perceived as unpleasant, demanding, scary, or threatening. The latter can include recalls of previously experienced or unpleasant or pleasant events which either positively or negatively influence the regulation of the HPA axis. Thus, stress leads to increased integrated cortisol and CA secretion, which can be of short or long duration depending on the severity and duration of the stressor. Following repeated exposure to stressors there is great interindividual variation in the extent of cortisol response habituation. Although studies have been conflicting with some showing activation and others attenuation of the HPA axis function in chronic stress, in both situations abnormalities of cortisol secretory dynamics are evident defining a chronic hyperactivation or hypoactivation of the stress system.

Overt or Subtle Hypercortisolism and Cardiovascular Disease

Excessive and sustained cortisol secretion or chronic administration of pharmacological doses of glucocorticoids (endogenous or exogenous Cushing's syndrome (CS), respectively) have been associated with the entire spectrum of the metabolic syndrome, including visceral obesity, insulin resistance/carbohydrate intolerance/DM2, dyslipidemia, dyscoagulation, and hypertension, along with their morbid sequelae of atherosclerosis and CVD. The causal association between chronic psychosocial stress, hypercortisolism, and metabolic syndrome-related manifestations has been shown experimentally only in cynomolgus monkeys. Major melancholic depression, a state of chronic and sustained hyperactivation of the stress system is also associated with hypercortisolism and such patients have a markedly decreased life expectancy due to increased mortality from CVD (2–3 risk of gender- and age-matched controls). Thus, sustained hypercortisolism, as encountered in CS and melancholic depression, is associated with increased prevalence of atherosclerosis, hypertension, and all the clinical and biochemical features of the metabolic syndrome and an overall increased in mortality from CVD.

The conspicuous similarities between CS and the metabolic syndrome and the development of atherosclerosis in both conditions suggest that hypercortisolism may be involved in the pathogenesis of the latter. There is some evidence that hypercortisolism may be directly related to the pathogenesis of the metabolic syndrome, as in such patients, alterations of the secretory pattern and turnover of glucocorticoids has been noted. Such patients may also have depressive (a severe form of chronic psychological stress) symptomatology and be at increased risk for developing a severe form of metabolic syndrome, depending on genetic, developmental and/or environmental factors. Indeed, some patients with depressive symptomatology and/or chronic active alcoholism associated with visceral obesity and insulin resistance and accompanied by increased cortisol secretion may occasionally be difficult to differentiate from those with frank endogenous CS. The term pseudo-Cushing syndrome has been employed to describe such patients. As depression is highly prevalent, affecting up to 10–15% of the population, a considerable number of patients with pseudo-Cushing are among us.

Increases in body mass index (BMI), blood pressure, and dyslipidemia in nonCushingoid middle-aged men have been correlated with the degree of stress perception and cortisol secretion. It is probable that similar parallel alterations of the other peripheral component of the stress system, the SNS, are also present.

CAs are important modulators of corticotropin-releasing hormone (CRH) and adrenocorticotrophic hormone (ACTH) secretion, particularly during acute and chronic stress and their effects are mediated by both the $\alpha 1$ and $\alpha 2$ subtypes of adrenoceptors. Activation of the $\alpha 2$ subtype may represent a negative-feedback mechanism that prevents excessive glucocorticoid responses to internal and external stressors. Indeed, following $\alpha 2$ inhibition, the ACTH response after combined stimulation with CRH and antidiuretic hormone (AVP) was significantly higher in obese (visceral obesity) compared to normal weight individuals. This finding suggests that obese individuals with abdominal fat distribution may escape the physiologic $\alpha 2$ -adrenoceptor control of their stress system, thus favoring inappropriate HPA axis and SNS excitation (Table 1).

Analyzing further the dynamics of cortisol secretion, it is evident that a nonstressed HPA axis is characterized by an increased variance of circadian cortisol secretion and an appropriate suppression of the morning cortisol levels in response to low-dose dexamethasone administration. In contrast, a chronically stressed HPA axis is characterized by a decreased diurnal variance, mostly due to evening elevation, mild morning decreases of cortisol levels, and inadequate suppression of morning cortisol by overnight dexamethasone. These findings suggest the presence of chronic hypersecretion of CRH in chronically stressed individuals and a reset of their HPA axis leading to an increase of total time-integrated cortisol secretion. In the presence of a properly functioning glucocorticoid negative-feedback system, these alterations of cortisol secretion are minimized resulting in amelioration of the manifestations of chronic hypercortisolism (Tables 1 and 2).

The ability of the glucocorticoid negative-feedback system to limit the production of cortisol during stress can be impaired by early life stress and by exposure of the organism to chronic physical/emotional stress. The sensitivity of target tissues to glucocorticoids, of course, also plays a major role in both influencing the negative-feedback system and the actions of glucocorticoids on their other target tissues. Studies examining the presence of polymorphisms of the glucocorticoid receptor gene described the presence of a correlation between particular polymorphisms and the development of hypertension and/or visceral obesity, whereas others demonstrated that increased dermal tissue glucocorticoid sensitivity was associated with an increased blood pressure, insulin resistance, and hyperglycemia. Interestingly, the same subjects also exhibited an enhanced secretion of cortisol and impaired conversion of cortisol to inactive

Table 1 Somatic consequences of chronic stress system activation/target tissue effects with respect to the development of CVD

HPA axis – cortisol	Locus caeruleus/ norepinephrine CAs, IL-6
<i>CNS effects</i>	
Potential of amygdala/fear – mesocorticolimbic dopaminergic system dysfunction (↑)	↑CAs
Leptin actions ↓

metabolites implying a direct or an indirect effect of stress on tissue active hormone availability.

Recent studies have shown alterations of 11β-hydroxysteroid dehydrogenase (11β-HSD) type 2, which converts cortisol to inactive cortisone, particularly in the kidney. However, the metabolic clearance rate of cortisol is mostly influenced by its regeneration from inactive cortisone in the liver, fat, and skeletal muscle by 11β-oxoreductase type 1. Consistent with animal studies, 11β-HSD2 appears to be a constitutive rather than a hormonally regulated enzyme, in contrast to 11β-HSD1 which is downregulated by insulin and estrogens and appears to be dysregulated

in obesity. The activity of 11β-HSD1 in the omental fat of obese people is significantly higher than in lean individuals and the activity of the enzyme is further increased by exposure to cortisol and insulin. The inappropriate constant exposure of fat, particularly visceral fat, to cortisol may be important in determining its differentiation and mass increase leading to visceral obesity and the manifestations of the metabolic syndrome. In addition, it may modify the secretion of other adipose tissue hormones, such as leptin, IL-6, and/or adiponectin, and thus modify the output of adipose cells and influence the information they convey to satiety centers regarding fuel homeostasis.

High circulating cortisol levels or sustained alteration of the normal diurnal pattern of cortisol secretion also suppress the growth, thyroid and reproductive axes and lead to elevation of Ca^{2+} -stimulated cytokine production (and particularly IL-6) contributing further to the exacerbation of the metabolic syndrome by inducing lipolysis and utilization of protein for glyconeogenesis. Activation of the stress system is associated with suppression of growth hormone secretion and resistance of somatomedin C and other growth factor effects on their target organs. The reproductive axis is also inhibited at several levels by various components of the HPA axis. Either directly or via β -endorphin, CRH suppresses luteinizing hormone releasing hormone (LHRH) neurons, and thus gonadotropin secretion from the pituitary gland, whereas glucocorticoids exert inhibitory effects at the levels of LHRH neurons, pituitary gonadotrophs and the gonads and render target tissues of sex steroids resistant to these hormones. These effects and similar ones observed in the thyroid axis, counteract the beneficial effects these hormones may exert in body distribution and fuel homeostasis contributing further to the development of visceral obesity and the metabolic syndrome by antagonizing fat-tissue catabolism and inhibiting muscle and bone anabolism.

Although alterations of the LC-NE-SNS have not been studied in such detail as those of the HPA axis, it is quite likely that SNS hyperactivity, either as a result of a generalized activation of the stress system or as a compensatory mechanism in cases of a faltering HPA axis activity, also participates in the pathogenesis of cardiovascular disorders. A consequence of elevated SNS activity may be through elevated free fatty acid levels which can induce insulin resistance in muscle and amplify the metabolic perturbations of patients with pathological regulation of their HPA axis (Table 1).

Systemic Inflammation and Cardiovascular Disease

Over the last decade, there is mounting evidence that inflammation plays a major role in the development of CVD. Several studies have documented that elevated concentrations of IL-6 or the downstream acute phase reactant C-reactive protein (CRP) predict the development of CVD over many years, suggesting that inflammation makes a contribution to the earlier stages of the disease. Elevated IL-6 levels can predict total and cardiovascular mortality over a 5-year follow-up, the association being independent of prevalent vascular disease, smoking, and traditional risk factors. The predictive value of IL-6 is in fact stronger than that of CRP. This cytokine is not produced only as a result of inflammation but as a component of

noninflammatory stress, while a large proportion of total circulating levels of IL-6 may originate from the adipose tissue. IL-6 participates in the development of CVD through different mechanisms, including induction of endothelial dysfunction, hepatic fibrinogen release, and adhesion molecule expression by endothelial cells and circulating leukocytes. IL-6 also decreases insulin sensitivity of peripheral tissues and increases circulating nonesterified fatty acids, inducing a metabolic syndrome phenotype. Psychological stress can elevate IL-6 levels through Ca^{2+} hypersecretion, possibly from liver Kupfer cells or from the adipose tissue itself. IL-6 is also a potent stimulator of the HPA axis leading to cortisol hypersecretion and the development of the metabolic syndrome through this path as well. It is possible that genetic variations of the IL-6 and other related genes involved in its signaling system modulate the body's response to stress and obesity.

Obesity as a Chronic Inflammatory State

Obesity is the most common and costly nutritional problem in the United States, affecting approximately 33% of the adult population while its incidence among children and adolescents is also rising. Obesity, particularly the visceral type, is the most important potentially preventable factor that substantially increases the risk for developing DM2, CVD, and certain types of cancers. Adipose tissue secretes large amounts of tumor necrosis factor (TNF)- α and IL-6 in a neurally, hormonally, and metabolically regulated fashion. The plasma levels of these cytokines are proportional to the BMI and are further elevated in patients with visceral obesity. The secretion of inflammatory cytokines has a circadian pattern, with elevations in the evening and in the early morning hours. This pattern is maintained in obese subjects, albeit at a higher level, is affected by the quality and quantity of sleep, and correlates with manifestations of the sickness syndrome. Thus, in obesity, hypercytokinemia is frequently associated with sleepiness and fatigue, as well with an activated acute-phase reaction. Obesity, especially the visceral type, can be considered as a chronic inflammatory state, with many of the behavioral, immune, metabolic and cardiovascular manifestations and sequelae of such a state.

Psychosocial Stress and Cardiovascular Disease

There has been considerable information relating alterations in the activity of the stress system and conventional risk factors in developing CVD, the major cause of morbidity and mortality in western societies. A consistent and continuous gradient between socioeconomic status (SES) and the prevalence

of CVD has been found, with people from lower SES having more disease. In some studies the ratio of death rates from the lowest to the highest professional grade may be as high as 3 to 1. Although an inverse relation between SES and cigarette smoking has been noted, this is not obvious when total cholesterol and/or blood pressure are considered; however, an inverse relation between SES and BMI and visceral obesity was noted as well. Not surprisingly, physical inactivity was clearly linked to obesity and lower SES and this combination may contribute further to the SES-disease gradient. In favor of these observations is the finding of the Gothenberg Primary Prevention Study, which demonstrated an odds ratio of CVD morbidity of 2.2, which changed to only 1.9 after adjusting for established risk factors (including blood pressure, smoking, cholesterol, BMI, and exercise habit). The inability of traditional risk factors to explain more than 25% of the SES-CVD gradient suggests that additional factors related to the working conditions might contribute.

The ability to monitor surrogate markers of CVD and also to visualize atherosclerotic plaques directly has helped to evaluate the biologic pathways through which SES may exert its effects. An analysis of psychological factors and blood pressure reactivity (measured as the anticipatory increase in blood pressure before an exercise test) exhibited a clear relation to progression of atherosclerosis. Chronic psychosocial stress directly through the stress system and its hormones and/or indirectly through changes in health-related behaviors may be the main culprit connecting poverty and CVD.

Caregiving Burden

The Stress Process

Longitudinal Effects of Caregiving

Psychosocial Interventions for Caregivers

Glossary

<i>Burden</i>	The emotional, psychological, physical, and financial challenges assumed by caregivers.
<i>Caregiver</i>	Person who provides informal (i.e., unpaid) assistance provided to a disabled individual, such as an adult child providing help to an elderly parent with Alzheimer's disease or an associated dementia.
<i>Objective burden</i>	The disruptions and degree of changes caregivers experience in various life domains.
<i>Stress process model</i>	A multidimensional framework that examines the proliferation or spread of stress from care-related dimensions to other life domains to global indicators of well-being.
<i>Subjective appraisals/burden</i>	Emotional reactions to stressors, such as fatigue or feelings of being trapped.
<i>Wear and tear hypothesis</i>	Posits that the longer a caregiver remains in her or his role, the more likely it is that negative outcomes will occur.

With increasing longevity and improvements in medical treatment for a range of chronic diseases, more people are surviving to advanced ages. Although most older people are healthy and independent, a significant minority suffer from a variety of physical, cognitive, and psychiatric disabilities that require regular ongoing care and supervision. Despite the visibility of nursing homes and other institutions, families provide the largest part of informal (i.e., unpaid) long-term care assistance to disabled older adults in the United States, and a major emphasis of public care policy is to keep older

adults in community settings and under the care of families or other informal providers in order to reduce the need for nursing home care.

Families have always cared for their elders, but changes in contemporary society have placed increasing strains on their resources to provide assistance. Elders are living longer after the onset of disabilities, and many suffer from severe chronic disabilities that necessitate extensive care. With women increasingly employed outside the home, the role of caregiver falls either on a spouse, who may have his or her own age-related limitations, or on a daughter or daughter-in-law, who must balance the multiple roles of worker, homemaker, caregiver, and, in some cases, mother to her own young children. It is not surprising, then, that much of the emphasis in research on caregiving has focused on the stressors and emotional strains of informal care. Early research focused on correlates of burden, or the emotional, psychological, physical, and financial challenges assumed by caregivers, as well as caregivers' subjective appraisals of how task performance affects their lives. However, the past two decades have seen the development of sophisticated conceptual models to capture the longitudinal dynamics of family care, as well as the development of psychosocial interventions to alleviate negative outcomes in informal long-term care systems.

Caregiving Burden

Early research on family caregivers to older adults suffering from chronic illnesses such as Alzheimer's disease often attempted to correlate contextual variables (e.g., duration of care, relationship of caregiver to care recipient) and care demands (e.g., severity of behavior problems, intensity of cognitive impairment, extent of activities of daily life [ADL] dependencies) with unidimensional constructs representing burden. Burden was often operationalized as the caregiver's subjective experience of care demands. Subsequent research suggested that burden was a multidimensional construct, with objective and subjective components. Objective indices of burden reflect the disruptions and degree of changes caregivers experience in various life domains, while subjective burden refers to caregivers' emotional reactions to care demands. Studies that incorporate this conceptualization of burden have found that different factors are associated with objective and subjective burden, underscoring the theoretical usefulness in approaching the demands of caregiving as multifaceted.

Other research has moved beyond the caregiver's subjective experience to consider the physiological effects of stress. The chronic stress of caregiving has been found to increase a caregiver's risk for health problems. This increased risk of illness is attributable to an overproduction of stress hormones and/or a decline in the use of preventative health measures by the caregiver, such as having annual physical exams, exercising, and having a healthy diet. Research examining caregiving at other points in the life span suggests that the burdens associated with informal care provision to a chronically ill care recipient can have negative implications at the cellular level, including shortened telomere length, reduced telomerase activity, and increased oxidative stress.

The Stress Process

With the greater concern given to the multidimensionality of caregiving stress and the various factors that account for such outcomes, conceptual models were developed to capture the process of informal long-term care. Perhaps the most noteworthy model is the stress process model (SPM), which is largely grounded in sociological perspectives of stress. Specifically, this approach suggests that the occurrence of some environmental demand that is potentially harmful (primary objective stressor) has an immediate impact on the caregiver's life (primary subjective stressor), for example, leading to feelings of overload or to the loss of valued aspects of the relationship with the other person. This immediate impact may proliferate into other areas of life (secondary role strains), for instance, interfering with employment or creating conflict in the family, and thereby increase the likelihood of poor adaptation (e.g., negative mental or physical health outcomes). Conversely, resources such as social support and coping skills can contain the primary stressors, limiting their impact on other roles and relationships and on well-being. Although this model was developed specifically for caregivers of Alzheimer's patients, its grounding in general sociological theory makes it potentially applicable to caregivers of older adults with other kinds of disabilities and impairments.

Longitudinal Effects of Caregiving

Much of the literature on caregiving is cross-sectional, that is, a one-time snapshot of the caregiver's situation. Many of these studies have attempted to explore the wear and tear hypothesis, which posits that the longer a caregiver remains in her or his role, the more likely it is that negative outcomes, such as caregiver

distress or even care recipient institutionalization, will occur. Longitudinal studies, however, make it possible to examine the dynamic interplay of stressors and adaptation. These studies support more complex views of the longitudinal progression of caregiving than that suggested by the wear and tear hypothesis. Several panel studies of dementia caregiving have found an adaptation effect, in which caregivers who remain in the role report decreases in negative emotional and psychological outcomes, such as burden and depression. These studies have supported counter hypotheses that emphasize the ability of families to tolerate once stressful situations or to adapt to and successfully manage chronic caregiving demands and stressors.

Other analyses have examined various transition points that can occur in informal long-term care, such as onset, institutionalization, and bereavement. While few analyses consider onset of informal care responsibilities, recent research suggests that individuals who experienced less abrupt entries into their caregiving roles are more likely to delay nursing home placement as well as indicate decreases in emotional distress and depression over time. Such findings imply that how people assume care responsibilities or manage problems early in their careers has important longitudinal implications, particularly in chronic diseases.

Given the potential public and private costs of nursing home placement, a number of studies have examined the influence of caregiving indicators (e.g., stress, sociodemographic context) on institutionalization. Several indicators have been identified as potential triggers of nursing home placement. Caregiving stressors (such as feelings of overload or feeling trapped by caregiving responsibilities), depression, or impaired subjective health appear likely to expedite placement and, in some instances, appear more likely to trigger institutionalization than functional indicators of the older care recipient. Other promising work in this area has emphasized that institutionalization is not an endpoint in caregiving. Caregivers remain involved in care and various dimensions of emotional distress and psychological well-being are relatively stable after nursing home placement. Similar studies have emphasized the complex progression of stress and depression of informal caregivers prior to and following bereavement.

Psychosocial Interventions for Caregivers

A major emphasis in the field has been the development of programs, services, and other interventions

designed to relieve the stress of caregivers. Increasingly, these interventions have used stress theory to identify modifiable features of the stress process that can lead to improved outcomes. The most successful interventions with caregivers have been multidimensional, addressing several dimensions of the stress process. Another common component of these interventions has been inclusion of the wider family network in treatment, usually through one or two family meetings. Help from families may be particularly useful, since it is flexible and personal. Family level interventions can also address conflict and misunderstandings about the nature of the elder's disease or how care is being provided. Outcomes of these interventions have included reduced subjective burden, lower negative appraisals of the elder's behavior, decreased depression, and delayed institutionalization. Some of these effects have been found to persist or even increase for 3 years or more beyond the intervention period. Interventions designed to reduce depressive behaviors for elders with comorbid depression and dementia have also been found to have corresponding benefits for caregivers' own feelings of depression and subjective burden.

Another way of addressing the stress on family caregivers is by initiating formal, paid help. A variety of services are available to elders and their families, including care management, in-home respite, and adult day services. The impact of these programs on caregivers' stress and well-being has been mixed. It is often the case, however, that caregivers included in these studies have received only low levels of assistance. In the one study that controlled for amount of exposure to the intervention, caregivers who used adult day services on a regular basis for 3 months or more experienced decreased overload, emotional strain, and depressive symptoms compared to a control group. This issue of therapeutic exposure is particularly relevant for caregiving research. Caregivers who are faced with multiple, chronic, and severe stressors are not likely to gain much benefit from brief or unfocused interventions.

Role of the Catecholamines
Summary and Conclusions

Glossary

<i>Dopamine</i>	A transmitter in the central nervous system, with at least five receptors (D1–D5). Dopamine is also a precursor to the formation of epinephrine and norepinephrine and influenced by stress, but generally not considered a stress hormone.
<i>Epinephrine</i>	A stress hormone secreted from the adrenal medulla in response to stimulation from the sympathetic nervous system. It activates both α - and β -adrenoceptors, with effects on heart rate and dilatation of blood vessels in the muscles and constriction of blood vessels in the skin.
<i>Lipolysis</i>	Refers to the release of lipids into the blood stream.
<i>Norepinephrine</i>	A stress hormone secreted from the adrenal medulla that also serves as a neural transmitter in the sympathetic and central nervous system. Most of the circulating levels of norepinephrine are produced by sympathetic nerve endings. Norepinephrine mainly affects α -adrenoceptors causing constriction of blood vessels and increases in blood pressure.
<i>Sympathetic adrenal medullary (SAM) system</i>	The sympathetic adrenal medullary system, where the catecholamines epinephrine and norepinephrine are secreted.

Catecholamines have been of central interest and importance in stress research since the first demonstrations of the role of sympathetic arousal in response

to stress exposure early in the twentieth century. Numerous animal experiments have illustrated the active defense reaction and the emergency function of the adrenal medulla, which increases the organism's chances of survival by fight-or-flight. During the past decades, a considerable number of studies in humans, in laboratory as well as in natural settings, has confirmed and extended the conclusions from animal studies. The aim of this article is to summarize research and conclusions relevant to the role of catecholamines in stress and health, including their assessment and methodological considerations, as well as gender differences in catecholamine responses to stress.

Role of the Catecholamines

Secretion of the catecholamines is regulated by mental influence (from the cortex) on the hypothalamus in the central nervous system, which activates the sympathetic adrenal medullary (SAM) system. Walter B. Cannon first demonstrated the important role of sympathetic activation in emotional responses to stress exposure. Norepinephrine was identified later by Ulf von Euler (1948). On the basis of animal experiments, Cannon described the fight-or-flight response or the emergency function of the adrenal medulla. The SAM system is activated when the individual is challenged in its control of the environment and this defense reaction prepares the body for battle. Catecholamines do not cross the blood–brain barrier but exert their effects peripherally.

The cardiovascular and neuroendocrine functions activated by catecholamines mobilize energy to the muscles, heart, and brain and, at the same time, reduce blood flow to the skin, internal organs and gastrointestinal system. In response to physical threat this is an efficient means for survival as it increases the organism's capacity for fight-or-flight. In modern society, however, elevated catecholamine levels are probably more often caused by threats of a social or mental rather than physical nature. In general, mental efficiency is also positively associated with elevated catecholamine levels. Mental stress is a very potent stimulator of epinephrine output, whereas

norepinephrine, having an important role in blood pressure homeostasis, is more closely associated with physical activity and demands and body posture.

Numerous studies from laboratory experiments, as well as from natural settings, illustrate the sensitivity of the catecholamines to various physical, psychological, and psychosocial conditions in humans and animals. In experimental studies, catecholamine responses have been examined in response to physical stressors, such as noise, electric shocks, heat, cold, and so on, and to mental and cognitive stressors, such as performance tests, harassment, cognitive conflict, time pressure, monotony, fear, and anticipation of stress. The influence of various real-life conditions on catecholamines have been investigated during daily stress at work, home, school, day-care centers, hospitals, on commuter trains or buses, and during intense stress induced by, for instance, parachute jumping, child birth, and the defense of a doctoral thesis.

Health and Behavior

Catecholamines and their concomitant effects on other physiological functions, such as blood pressure, heart rate, and lipolysis, may serve as objective indicators of the stress that an individual is exposed to. However, these bodily effects are also assumed to create a link between psychosocial stress and increased health risks. Lasting elevated catecholamine levels are considered to contribute to the development of atherosclerosis and predispose to myocardial ischemia. The elevated catecholamine levels also make the blood more prone to clotting, thus reducing the risk of heavy bleeding in case of tissue damage but at the same time, increasing the risk of arterial obstruction and myocardial infarction. The role of the catecholamines in hypertension is also of great importance.

Elevated catecholamine secretion in response to challenge has been demonstrated for the stress-related and coronary-prone type A behavior pattern. Additional support for a role of the catecholamines in the development of coronary heart disease (CHD) is obtained from studies showing that high job strain (high demands and low control) and high catecholamine levels are related to elevated risk of CHD. Catecholamine activation is also known to interact with the other major neuroendocrine stress system, namely, the hypothalamic-pituitary-adrenal (HPA) axis and the secretion of cortisol, and form an integrated stress response, which seems to potentiate several health risks including CHD. Negative emotional stimulation activates via higher brain centers both the secretion of catecholamines and cortisol. High epinephrine levels seem to enhance the HPA response and low levels to diminish it and, the corticotropin releasing hormone

(CRH), which activates the HPA axis, also seems to stimulate sympathetic outflow.

Catecholamines also serve an important role in human performance and behavior. The secretion of the catecholamines is not only related to the individual's physical capacity, but also to factors such as mental effort and cognitive performance. Under normal levels of stress and arousal, a further increase in catecholamine output is associated with improved performance, whereas under conditions of very intense stress, additional increase in catecholamine output may cause deterioration in mental functioning and disorganized behavior. In summary, the level of performance and mental wellbeing can be described as an inverted-U function of the intensity of stress, which means positive correlations with catecholamine secretion at low and moderate levels of stress and negative at very high levels. The optimal level of performance is located at higher stress levels for simple tasks compared with more complex ones, and varies between individuals depending on personality characteristics, mental state, and so on.

Assessment

Blood levels of catecholamines change rapidly (within 1 minute) in response to stress exposure. A small but relatively constant fraction of the circulating levels of epinephrine and norepinephrine in the blood is excreted into the urine. Consequently, assessment can be made from blood (usually plasma) as well as from urine. In general, results from studies based on blood and urine samples are highly consistent, showing significant positive relationships between changes in urinary and plasma catecholamines in response to stress.

Plasma catecholamine levels readily reflect acute stress responses during exposure to short-term stress and have been used extensively in animal research. Urinary catecholamines also respond rapidly to stress exposure but, depending on the time between urine sampling, the urine in the bladder provides an integrated measurement representing the mean stress level for a more extended period of stress exposure. Using voluntary voiding, the normal period between urine sampling is 2–3 h, which means that urinary catecholamines are preferable for the study of longer periods of stress or chronic stress exposure. A normal procedure for studying long-term stress could involve taking urine samples at regular intervals over days or weeks.

Due to the rapid changes in plasma catecholamine levels, frequent blood sampling via an indwelling catheter is necessary in order to obtain representative measures of circulating levels for longer periods of time, which is usually not feasible in, for example, the

study of work stress. Other problems associated with venipuncture are that norepinephrine concentrations vary between sampling sites due to differences in regional blood flow and reuptake by the nerve terminals, and that blood sampling in itself may cause increased levels of epinephrine secretion.

For methodological reasons, human plasma catecholamines have been studied almost exclusively in the laboratory, whereas urinary catecholamines have been used extensively in the study of human stress in natural settings. The advantages of urinary measurements in the study of, for example, work stress, are that they do not interfere with the subject's normal habits and environment and that they cause no harm or pain to the subject. In addition, integrated measurements are provided for longer periods of time – relevant for the study of the psychosocial stress associated with different conditions at work.

The amount of urinary catecholamines excreted during a particular period of time can be determined by the concentration of the sample, multiplied by the total urine volume. Thus, in the study of urinary catecholamines, the total volume of the sample has to be measured after voiding. In addition, the pH level of the urine should be adjusted to about 3.0 (using acid) to prevent the catecholamines from deterioration. The acidified urine sample should then be kept frozen (−18 °C) until analyzed.

In cases where the time between voiding of urine is unknown or the total volume of the sample has not been properly measured, the catecholamine concentration can be related to a reference substance such as creatinine, which is considered to be secreted at a constant rate. Provided that reliable measurements are obtained and the subject is able to empty his or her bladder completely, the results from these two methods are highly correlated. The most common method for catecholamine assessment in blood or urine is high-performance liquid chromatography (HPLC) with electrochemical detection. This and other modern methods (e.g., enzymatic methods) have high sensitivity and specificity. An earlier method used extensively during the period 1960–80 is the fluorophotometric method of Euler and Lishajko, which is reliable for the determination of urinary catecholamines but not sensitive enough for the analysis of plasma, where the concentration of the catecholamines is lower.

Methodological Considerations and Confounders

Catecholamines have a pronounced circadian pattern, which has to be taken into consideration in the study of responses to stress. Under normal night-sleep–day-wake conditions, the catecholamines peak

in the middle of the day and reach their lowest levels during night sleep. The circadian rhythm of epinephrine remains relatively stable even during several nights of sleep deprivation, whereas norepinephrine is more influenced by physical activity. Consistent changes in the sleep–wake pattern, for example in habitual night work or east–west traveling over 12-h time zones, will completely reverse the circadian rhythm of the catecholamines in about 1 week. Variations in shift work and frequent east–west flights will disturb the normal circadian rhythm and produce a flattened curve of catecholamine secretion as well as problems in staying alert and sleep disturbances. Other (nonpsychological) factors influencing catecholamine secretion are the intake of caffeine (coffee), alcohol, nicotine (cigarette smoking), medication (β -blockers, diuretics, etc.), and heavy physical exercise.

In the study of stress and catecholamines, the influence by confounders has to be controlled by requesting the participants to refrain from smoking, drinking coffee, and so on, or by controlling the effects on the catecholamines by asking the participants to consume the same amount of cigarettes and coffee in the control condition as in the experimental situation.

Moderate or small seasonal variations in catecholamines have been reported, as well as variations during the menstrual cycle. Norepinephrine levels have also been found to increase with old age. As related to weight, children have higher levels than adults, but as related to body surface area the excretion rates are relatively stable from the first years of life into adulthood.

Individual variations in baseline levels are pronounced but relatively stable over time. For instance, the highest epinephrine level may be 10 times greater than the lowest. This variation is likely to be related to individual differences in renal clearance and body weight, but psychological differences between individuals with high and low baseline catecholamine levels have also been reported. During mild stress, such as carrying out normal daily work, the epinephrine output increases by 50–100% above the resting level, whereas more severe mental stress and intense cognitive and emotional demands, such as child birth, may cause epinephrine to rise more than 10 times the resting level. There are no normal levels of catecholamine and no threshold limits, but clearly pathological levels can be found in association with, for example, adrenal tumors.

In order to reduce the influence of circadian rhythms and of individual differences in baseline levels, it is generally recommended that the individual's response to stressful conditions be compared with his or her corresponding baseline level. The two

measurements have to be obtained at the same time of day, which means that they must be made on separate days. By studying the relative change from baseline rather than absolute levels, the variation between individuals is considerably reduced and the statistical power is increased without having to increase the sample size.

Reliable baseline levels can be obtained in situations where the individual is alone and able to relax completely. In an experimental study this can be achieved by inviting subjects to come to the laboratory after the experimental session and making sure that they are confident that they will not be exposed to any kind of stressor. In order to help the subject to relax, a quiet environment, light entertainment with music and/or suitable reading material, as well as relaxation training can be used. In studying stress in natural settings, such as the work environment, baseline levels of catecholamines can be obtained by giving the worker a paid day off from work. He or she is then instructed to relax alone at home and avoid any activity that might contribute to stress, such as shopping, cleaning, taking care of children, heavy physical exercise, and so on.

Epinephrine secretion is particularly sensitive to novel stimulation and stress associated with anticipation. Exposure to the laboratory and the experimental equipment to be used may induce as high or higher epinephrine levels than the actual stress tests. This means that catecholamine levels before an experiment usually cannot be used as baselines. The anticipation and novelty effects can be reduced or eliminated by asking the subject to visit the laboratory before the experiment to become familiar with the methods of measurement and the equipment to be used. Similarly, at the workplace, the stress induced by the investigation *per se* can be avoided by performing measurements (urine sampling, etc.) one or several days before the actual data collection, to make the participants familiar with all aspects of the study.

Gender Differences

Up to 1970, almost all human studies were performed on men. However, when gender differences were studied in the early 1970s, men were consistently found to be more responsive to experimental stress by showing greater elevations in epinephrine than women. Although women performed as well or usually even better than the men on the various stress tests used in the experiments, their epinephrine secretion did not increase very much. During more intense stress (examination stress), the epinephrine output of women

was found to increase significantly, but still to a lesser extent than that of men in the same situation.

A possible explanation for these gender differences is that the performance tests used to induce stress were less challenging to women than to men. In keeping with this, it was found that emotional stress associated with accompanying a child to hospital had a more pronounced effect on the mothers' catecholamine levels. The importance of gender roles is also illustrated by the fact that women in male-dominated occupations and lines of education seem to respond to performance stress with epinephrine responses similar to their male colleagues. Recent studies comparing men and women matched for education and occupational level showed similar catecholamine responses to stress in women as in men.

Although, the possible influence of biological factors, such as steroid sex hormones, on catecholamine responses cannot be excluded, it seems as if psychological factors and gender role patterns, in general, are more important for the differences in catecholamine responses between men and women.

In men, a significant positive correlation is usually found between perceived stress and performance on the one hand, and catecholamine responses at work, on the other. The more intense or frequent the stress exposure at work the higher the catecholamine output. In women, however, corresponding relationships are more inconsistent. Stress exposure and catecholamine levels at work seem to spill over into nonwork situations. Women with high catecholamine levels at work tend to have high catecholamine levels after work, and women exposed to elevated work stress (e.g., by working overtime) have elevated catecholamine in the evening or during the weekend at home. A likely explanation for this is that there is a greater interaction between the stress from paid employment and unpaid work at home for women than there is for men. This has to be taken into consideration in the study of women's stress and workload.

Positive and Negative Stress

As described by Henry, activation of the SAM system and high catecholamine output are associated with an active coping style and dominant behavior among animals, whereas passive coping and the defeat reaction are associated with activation of the HPA axis, high cortisol levels, and submissive behavior. A similar but less consistent pattern of findings has been reported in humans. Recently, an association between high epinephrine and cortisol levels and low socioeconomic status has been found.

In human stress, epinephrine levels are significantly elevated by stress caused by over- as well as by understimulation, compared with more optimal environmental conditions. This means that work overload, a very high work pace, too much responsibility, role conflicts, as well as simple, monotonous and repetitive jobs or lack of meaningful activities (e.g., unemployment), may contribute to elevated epinephrine levels. However, as demonstrated by Levi, epinephrine output reflects the intensity of stress rather than its emotional valence. Intensive pleasant stimulation, such as watching a funny movie, may induce elevated epinephrine levels as well as does unpleasant stimulation.

Summary and Conclusions

The two catecholamines, epinephrine and norepinephrine, are very sensitive to behavioral, emotional, and cognitive stimulation and the magnitude of the response seems to be closely related to the intensity of perceived stress regardless of the emotional quality. Epinephrine mainly reflects mental stress, whereas norepinephrine is more sensitive to physical demands and body posture. Much less is known about the role of dopamine under stress, but several studies have shown that stress-induced dopamine effects have an important role in the pathogenesis of certain brain diseases and in drug addiction.

Catecholamines may thus serve as objective indicators of the intensity of stress that an individual is exposed to. However, they also play an important role in the development of several health problems and, thus, create a link between stress and disease. In order to obtain valid and reliable measurements, strict control of possible confounders is necessary at all stages of the process – preparing the subjects, determining baselines, collecting, preparing, and storing the samples, performing the hormone assay, and so on.

Overview of Stress: Inputs, Outputs, and Evaluative Processes

Hypothalamic-Pituitary-Adrenocortical (HPA) Axis

Initiation of the Stress Response

Termination of the Stress Response

Concluding Remarks

Glossary

<i>Homeostasis</i>	Maintaining constancy of the internal environment of the body.
<i>Stressor</i>	Stimulus input that initiates a stress response.
<i>Stress response</i>	A nonselective response (endocrine, behavioral, autonomic) that targets multiple tissues and organs in response to, or anticipation of, a challenge to homeostasis.

An understanding of central stress neurocircuits requires knowledge of neuroanatomical pathways that underlie detection of various stimuli leading to a stress state, perception of those inputs as stressful (when appropriate), and mediation of select response outputs. In this article, the basic neurocircuitry involved in regulation of the hypothalamic-pituitary-adrenocortical (HPA) axis is reviewed. The HPA axis mediates secretion of glucocorticoids in response to a variety of stimuli ranging from immune responses to hemorrhaging to social defeat. Thus, it is important to understand how such diverse stimuli can lead

to activation of the HPA axis. The stress-induced increases in glucocorticoids act to maintain homeostasis as well as to mobilize energy stores for fight-or-flight reactions. Although these actions can and do occur together, it is possible to isolate homeostatic regulation from the more global defense response. These phenomena can be distinct in terms of arousal, emotional salience, conscious perception, and behavioral responsiveness. As a consequence, it is also important to understand how the brain responds to different types of stressful events.

Overview of Stress: Inputs, Outputs, and Evaluative Processes

Stress has been described as a multidimensional concept consisting of three major components: the stimulus input, an evaluative process, and the response output. The stimulus input, or stressor, refers to an event that elicits a nonselective response (endocrine, behavioral, autonomic) that targets multiple tissues and organs in response to, or anticipation of, a challenge to homeostasis. In many cases, the link between stimulus inputs and response outputs requires perception of a given event as stressful. This evaluative process can include not only processing of stimulus-specific information and coding of the stressor's intensity and intermittency, but also comparison of the current situation to previous experiences. In addition, this evaluative process reflects the organism's ability to cope with the stressor (e.g., degree of controllability, real or perceived). The response output, or stress response, is the body's adaptations designed to re-establish physiological or psychological equilibrium. Depending on the particular stimulus input, a specific array of responses may be initiated ([Figure 1](#)).

This concept of stress has been modified to reflect the notion that some stimulus inputs can lead to a stress response without requiring evaluation. Consequently,

Figure 1 Schematic diagram illustrating the basic relationship between stimulus inputs and response outputs.

various authors in the field have classified stressors in distinct ways: physical versus psychological, or systemic versus neurogenic/processive. The key element associated with such distinctions is the need for a stimulus input to be perceived as stressful. For example, the experience of novelty as a mild stressor requires perception of a situation as different with the potential to encounter threatening stimuli. A novel environment would be classified as processive, involving higher order processing within the central nervous system in order to identify the present situation as unique in comparison to previous experiences. In contrast, other stimulus inputs are thought to elicit a stress response without prior evaluation. For example, hemorrhaging activates various reflexes designed to return blood volume to normal values. In this case, it is not necessary to perceive blood loss as stressful – the reaction is automatic. Hemorrhaging would be considered systemic, involving perturbations in homeostasis or a threat to an individual's internal environment.

Although stressors can be distinguished in terms of the type of stimulus input and the need for evaluative processing, a key component of the response output involves activation of the hypothalamic-pituitary-adrenocortical (HPA) axis. The HPA axis mediates release of glucocorticoids from the adrenal cortex, and glucocorticoids play an important role in energy metabolism and the maintenance of homeostasis. In this article, the basic elements of the HPA axis, including a description of specific brain pathways implicated in HPA axis regulation, are reviewed.

In this discussion, how the brain responds to two distinct stressors – an immune challenge, as an example of a systemic stressor, and social defeat, as an example of a processive and psychological stressor – is considered. Last, the article considers how a stress response is terminated, a process linked to distinct neurocircuits and stress-induced increases in glucocorticoids.

Hypothalamic-Pituitary-Adrenocortical (HPA) Axis

The HPA axis is involved in control of secretion of glucocorticoids from the adrenal cortex. Neurons within the medial parvocellular subdivision of the paraventricular nucleus of the hypothalamus (mpPVN) synthesize corticotropin-releasing hormone (CRH) and project to the median eminence, releasing CRH into hypophyseal portal blood vessels to reach specific cells within the anterior pituitary called corticotrophs. The binding of CRH to its receptor on the corticotroph's cell membrane stimulates a cascade of intracellular events leading to the release of adrenocorticotrophic hormone (ACTH) into the general circulation. CRH is the major ACTH secretagogue, although a number of additional molecules have been implicated in facilitating ACTH release (e.g., vasopressin). ACTH acts upon specific receptors in the adrenal cortex to stimulate the synthesis and release of glucocorticoids into the general circulation. Depending upon the species, the major glucocorticoid secreted from the adrenal cortex may be cortisol (human), corticosterone (rat), or both (hamster).

Initiation of the Stress Response

A variety of approaches have been taken to identify brain regions involved in regulation of the HPA axis. Our current state of knowledge is based upon studies that have utilized tract tracing to identify afferent inputs into the mpPVN, expression of immediate early genes to identify activated brain regions, lesions to determine the importance of a given set of inputs for stress-induced glucocorticoid secretion, and pharmacological and biochemical analyses to determine the role of particular neurotransmitters and neuropeptides in HPA axis regulation. Several key findings obtained from these data are summarized in [Figures 2 and 3](#).

Is there a common set of pathways within the central nervous system critical for initiating a stress response, or do different stressors activate the HPA axis through distinct neurocircuits? The data collected, thus far, provide evidence in support of both arguments. Indeed, systemic (physical) and processive (neurogenic/psychological) stressors appear to activate the HPA axis largely through distinct pathways, although this does not preclude the possibility that multiple pathways may be involved, especially for

complex stressors that have both physical and psychological components. Within the class of processive stressors, similar activation patterns are generally observed, possibly reflecting, at least in part, the activation of core neurocircuits critical for glucocorticoid secretion.

Homeostatic Regulation: Systemic, Physical Stressors

Stressors that are systemic or physical in nature involve a reaction to a threatening stimulus in an individual's internal milieu leading to the activation of regulatory mechanisms that serve to restore homeostasis. A variety of stimulus inputs is under homeostatic control, including body temperature, immune responses, and changes in blood volume and composition. For many of these stimuli, it is absolutely critical that the levels of these variables be maintained within a certain range for survival. Because of this link to survival, systemic stressors are associated with activation of brainstem and circumventricular afferents that have direct projections to mpPVN neurons. In many cases, excitation of the HPA axis is dependent upon ascending catecholaminergic input.

Figure 2 Schematic diagram summarizing the role of brain stem and circumventricular afferents in regulation of the functional activity of mpPVN neurons. This afferent input has been associated with activating the HPA axis in response to systemic and physical stressors.

Figure 3 Schematic diagram summarizing the role of BST, MPOA, and hypothalamic and limbic afferents in regulation of the functional activity of mpPVN neurons. The limbic system has been linked to activating the HPA axis in response to processive and psychological stressors.

For example, activation of an inflammatory or immune response increases the production and release of various cytokines (e.g., interleukin-1 β), which leads to excitation of the HPA axis. This rise in glucocorticoids is an adaptive response that serves to inhibit the immune system, limiting its scope of attack and decreasing the likelihood that the immune system will attack self. **Figure 4** illustrates the general pattern of *c-fos* mRNA expression that occurs within the brain of a male rat 30 min following systemic administration of interleukin-1 β (IL-1 β). As evident from the photomicrographs, the pattern of neuronal activation is fairly localized, with increased expression of *c-fos* mRNA observed within bed nucleus of the stria terminalis (BST), central amygdaloid nucleus (CeA), mpPVN, parabrachial nucleus (PBN), nucleus of the solitary tract (NTS), circumventricular organs including area postrema (AP), and barrier-related structures including meninges, cerebral vasculature, and choroid plexus. Additional studies have reported activation of neurons within the medial preoptic area (MPOA), supraoptic nucleus of the hypothalamus (SON), magnocellular and autonomic subdivisions

of PVN, thalamus, and catecholamine cell groups of the ventrolateral medulla (VLM; A1 and C1 cell groups) and NTS (A2 and C2 cell groups).

Increased expression of *c-fos* mRNA within the PVN presumably reflects excitatory control of the pituitary–adrenocortical axis in response to systemic administration of IL-1 β . Catecholaminergic input from the NTS and ventrolateral medulla is critical for activating mpPVN neurons in response to IL-1 β , as lesions that destroy these ascending pathways can drastically reduce *c-fos* expression within mpPVN neurons and other measures of HPA axis activity. In accordance, *c-fos* mRNA levels are increased within neurons of the adrenergic (C1, C2) and noradrenergic (A2) cell groups, and retrograde tract-tracing studies have shown that the majority of these activated neurons project to mpPVN. Systemic administration of IL-1 β can activate these catecholaminergic cell groups via two main pathways. The NTS receives visceral sensory information carried by the vagus and glossopharyngeal nerves, and there is evidence that these sensory afferents can respond to IL-1 β in the periphery. In addition, neurons within the area

Figure 4 Series of photomicrographs illustrating the location of *c-fos* mRNA within the brain of a male rat following systemic administration of interleukin-1 β . Note the selective pattern of neuronal activation with increases in *c-fos* mRNA present within the bed nucleus of the stria terminalis (BST), paraventricular nucleus of the hypothalamus (PVN), central nucleus of the amygdala (CeA), nucleus of the solitary tract (NTS), and area postrema (AP). PBN, parabrachial nucleus.

postrema can transduce IL-1 β present in the bloodstream into a neural signal that is then transmitted to neurons within the NTS and VLM. In support of this second pathway, *c-fos* mRNA levels are elevated within the area postrema in response to IL-1 β .

The lateral subdivision of the CeA and the dorso-lateral or oval nucleus of the BST (BSTov) also show prominent activation following IL-1 β administration. Both of these brain regions have been implicated in stress responses, particularly autonomic responses, but it is unclear what their role is in the response to IL-1 β administration. They are unlikely to be the primary regions involved in the increase in HPA axis activity for several reasons. First, neurons within the lateral CeA do not project to the PVN, but rather to three main regions – medial CeA, restricted parts of the BST (including the oval nucleus), and the parabrachial nucleus in the pons. Second, while tract-tracing studies show a significant proportion of cells within the NTS and VLM that project to mpPVN and contain Fos protein, a similar finding is not observed for neurons within the CeA or BST. Third, administration of indomethacin, a prostaglandin synthesis inhibitor, blocks the ability of neurons in area postrema to transduce IL-1 β into a neural signal. This effect results in decreased activation of neurons within NTS and VLM, leading to decreased activation of mpPVN neurons and a reduction in ACTH release. However, indomethacin administration does not reduce *c-fos* expression within CeA, suggesting that the mechanisms associated with HPA axis regulation in response to IL-1 β administration are distinct from those controlling activational processes within CeA. That said, there is some evidence to suggest that the ventral BST modulates the HPA axis response to IL-1 β and that the CeA may modulate this BST region.

Fight or Flight Response: Processive, Psychological Stressors

Stressors that are processive and psychological in nature involve a reaction to a real or perceived threatening stimulus in an individual's external environment. Such reactions are associated with increased arousal and vigilance, often eliciting a state of fear (or increased anxiety) and, in many instances, leading to a global response output that has been termed fight or flight. The image conveyed by fight or flight is one of an active state – secretion of glucocorticoids and other neurohormones, activation of the sympathetic division of the autonomic nervous system leading to increases in heart rate, blood pressure, and respiration, and display of behavioral responses designed to effectively cope with the threatening event.

A processive stressor requires the processing of exteroceptive signals from multiple sensory modalities that lead to perception of the stimulus input as stressful. This evaluative process may also reflect psychological variables, including predictability and controllability of the stressor as well as coping strategies. Because of this need for higher level processing, processive stressors are thought to activate limbic afferents that control HPA axis activity via synaptic connections with the BST, MPOA, and hypothalamus.

The effects of social defeat in the male Syrian hamster have been studied as one model of a processive, psychological stressor. Using a resident-intruder paradigm, the pairing of two isolated male hamsters results in fighting, with one male (dominant) behaving aggressively, attacking and chasing the other male (subordinate), which reacts submissively, defending against attack and displaying flight. The subordinate male is stressed as evidenced by elevated levels of glucocorticoids, while the dominant male is not. **Figure 5** illustrates the general pattern of *c-fos* mRNA expression that occurs within the brain of a socially defeated male 30 min after the onset of fighting. This series of photomicrographs reveals a global pattern of activity encompassing vast regions of the neocortex, septum, amygdala, hypothalamus, and brainstem. By analyzing *c-fos* mRNA expression within different control groups and in dominant and subordinate males, it is possible to identify patterns of neuronal activity associated with handling, fighting, and the stress of defeat. Activation observed in numerous brain regions in handled control, dominant, and subordinate males presumably reflects the detection of exteroceptive signals, leading to an increase in arousal and conscious awareness. In contrast, selective activation of brain regions in subordinate males most likely reflects processes associated with the perception of the stimulus input as threatening and stressful as well as mediation of various response outputs leading to the fight-or-flight response. In subordinate males, *c-fos* mRNA increased selectively within the cingulate cortex (medial prefrontal cortex), lateral septum, BST, MPOA, several hypothalamic nuclei (paraventricular, anterior, ventromedial, arcuate, and supramammillary), CeA, amygdalohippocampal area, periaqueductal gray, dorsal raphe, cuneiform nucleus, and locus coeruleus.

The limbic system plays an important role in regulating HPA axis activity in response to processive and psychological stressors. Following defeat, significant increases in neuronal activation were observed within mPFC, lateral septum, and amygdala. The hippocampus also plays an important role in HPA axis activity, although *c-fos* mRNA levels were not selectively increased within this brain region. This negative finding has been reported following other

Figure 5 Series of photomicrographs illustrating the location of *c-fos* mRNA within the brain of a male hamster following social defeat. Note the global pattern of brain activity observed throughout the brain. A selective pattern of neuronal activation was observed in the cingulate cortex (Cg), lateral septum (LS), bed nucleus of the stria terminalis (BNST), medial preoptic area (MPOA), paraventricular (PVN) and ventromedial (VMH) nuclei of the hypothalamus (PVN), central nucleus of the amygdala (CeA), and locus coeruleus (LC). MeA, medial nucleus of the amygdala.

stress paradigms. The majority of studies have linked mPFC, lateral septum, and hippocampus to inhibition of glucocorticoid secretion (see next section). In contrast, numerous studies have implicated the amygdala in excitatory regulation of the HPA axis. For example, electrical stimulation of neurons within the medial, cortical, and central nuclei have all been shown to stimulate glucocorticoid secretion. Furthermore, lesions of the medial and central nuclei can decrease ACTH and corticosterone secretion in response to stress. Following defeat, a significant increase in *c-fos* mRNA expression was observed within CeA. This increase is quite unusual for processive stressors, which in general produce quite meager or no increases in *c-fos* mRNA or Fos protein expression in this area. This is in contrast to systemic stressors such as IL-1 β , which cause robust increases of *c-fos* gene products in the CeA. In fact, recent evidence has suggested that many processive stressors, including novelty, loud noise, and restraint, inhibit the neurons in the CeA (and related BSTov). It is possible that brain activity following defeat reflects psychological and physical processes, with increased expression of *c-fos* mRNA within CeA (and dorsolateral BST) synonymous with brain activity observed following systemic or physical stressors (e.g., processing of painful stimuli associated with biting attacks).

Although activated neurons were also detected within the medial and cortical subdivisions of the amygdala, the levels present in subordinate males were not different from those observed in handled control or dominant males. It is at present unclear whether *c-fos* expression within the medial and cortical amygdaloid nuclei following social defeat reflects an increased propensity to stimulate glucocorticoid secretion that is differentially regulated at more central levels (e.g., enhanced in subordinate animals but inhibited in handled control and dominant males). Alternatively, activation within these brain regions may be associated with processes that are not specific to stress, such as coupling sensory cues with behavioral arousal.

While there is some evidence to suggest that the medial and central amygdaloid nuclei can project to the PVN, the input is limited and primarily focused toward autonomic subdivisions of this nucleus. The majority of anatomical studies suggest that the limbic system can influence the HPA axis via synaptic relays within the BST, MPOA, and hypothalamus. Indeed, lesions of neurons within the BST, MPOA, and hypothalamus have been shown to have either excitatory or inhibitory effects on HPA axis activity. Furthermore, tract-tracing studies reveal that many neurons within these three brain areas project directly to

the mpPVN. Following defeat, significant increases in *c-fos* expression were observed throughout the BST, MPOA, and hypothalamus. Additional work will be required to identify specific groups of neurons within these brain areas that are activated during defeat and that project to mpPVN.

The global pattern of brain activation seen following defeat is also observed in response to many other processive or psychological stressors, including conditioned fear, audiogenic stress, predator odor stress, footshock, restraint, immobilization, and swim stress. Following many of these stressors, significant increases in neuronal activation can be seen within various components of the limbic system. Several of these areas have been shown to correlate well with ACTH release following audiogenic stress, including the PVN, ventral lateral septum, medial and ventral BST, and medial preoptic area. It remains to be tested whether some or all of these areas form a core neural circuitry mediating the HPA axis response following processive stress.

Termination of the Stress Response

In addition to understanding how the HPA axis is activated during a stressful event, it is equally important to identify the mechanisms involved in terminating or limiting this response. Specific brain regions and stress-induced increases in glucocorticoids play an important role in terminating the stress response.

Neuronal Regulation

Local neurocircuits utilizing γ -aminobutyric acid (GABA) as a neurotransmitter have been implicated in inhibitory regulation of the HPA axis. Lesions placed within the BST, MPOA, or hypothalamus (including the arcuate, ventromedial, and suprachiasmatic nuclei) can increase the levels of ACTH and corticosterone secreted basally and in response to stress. All of these regions contain substantial populations of GABA-containing neurons, and, most recently, it has been shown that mRNA levels of the GABA biosynthetic enzyme glutamic acid decarboxylase increase within these brain areas in response to stress.

In addition, neurons within the lateral septum, mPFC, and hippocampus have also been linked to inhibitory regulation of the HPA axis. For example, lesions placed within any of these brain regions can prolong glucocorticoid secretion in response to stress. In addition, electrical stimulation of the hippocampus has been shown to inhibit glucocorticoid secretion. These data suggest that one function of these limbic brain regions may be to limit or terminate activity

within the HPA axis. The major neurotransmitter utilized by neurons within the mPFC and hippocampus is the excitatory neurotransmitter glutamate. It is possible that afferents from the mPFC and hippocampus act to excite GABA neurons within the BST, MPOA, and hypothalamus, leading to increased inhibition of the HPA axis.

Hormonal Regulation

Glucocorticoids act to inhibit the HPA axis at multiple levels: pituitary, PVN, and higher brain centers; and in different time domains: fast, intermediate, and slow (genomic). The genomic, and, to some extent, intermediate forms of inhibition appear to involve the classic mechanism of steroid–receptor-mediated regulation of gene transcription. Elevated levels of glucocorticoids bind to glucocorticoid receptors (GRs), activating the receptor and causing it to translocate to the nucleus where the steroid–receptor complex binds to DNA, leading to decreased transcription of CRH and AVP genes in the hypothalamus and decreased transcription of the POMC gene in the pituitary. The mechanisms that underlie fast feedback inhibition are not well understood. This form of inhibition occurs too rapidly to be explained by changes in gene transcription. It is possible that glucocorticoids act at GRs to mediate nongenomic effects, or, alternatively, glucocorticoids may interact with a different class of glucocorticoid-sensitive receptors (e.g., membrane receptors).

Glucocorticoids are also thought to act at higher brain centers to inhibit the HPA axis. For example, lesions of the hippocampus lead to an increase in the expression of CRH and AVP mRNA within mpPVN neurons, even though basal levels of glucocorticoids are elevated, suggesting that glucocorticoid negative feedback has been reduced following hippocampal damage. Lesions of the hippocampus have also been shown to attenuate the ability of exogenous glucocorticoids to inhibit secretion of stress hormones, although not all studies support this contention. Similarly, implants of glucocorticoids into the mPFC or MPOA have been shown to block restraint-induced secretion of stress hormones. These findings suggest that glucocorticoids interact with neuronal elements to increase inhibitory control over the HPA axis. How this effect is mediated at the level of neurons and neurocircuits is presently unknown.

Concluding Remarks

This article was designed to provide a general understanding of how the brain responds to an acute stress

exposure, highlighting important differences in brain activity in response to stressors that are systemic and physical in nature versus those that are processive and psychological. However, the relationship between stress and brain activity may be more complex than simply a reflection of the class of stressor involved. Indeed, how the brain responds to stress can be influenced by a number of associative factors, including the intensity, intermittency, chronicity, and context of the stress exposure as well as the individual's ability to effectively cope with stress. The challenge will be to understand how these more subtle aspects of stress responsiveness are coded within central stress neurocircuits.

Imaging Methods

Structural and Functional Brain Changes Associated with Stress-Related States

Conclusions

Glossary

<i>Amygdala</i>	Part of the temporal cortex; associated with anxiety and other emotional function.
<i>Atrophy</i>	Reduction in cell mass.
<i>Cingulate cortex</i>	Evolutionary old limbic cortex overlying the corpus callosum, whose fibers connect the two brain hemispheres.
<i>Cortisol</i>	A glucocorticosteroid.
<i>Dopamine</i>	A neurotransmitter related to motivation, movement, and emotion.
<i>Glucocorticosteroids</i>	Hormones secreted by the adrenal gland, related to stress.
<i>Hippocampus</i>	Evolutionary old part of the temporal lobe, associated with memory and emotional functions; part of the limbic system.
<i>Ligand</i>	Substance binding to a receptor, e.g., for a neurotransmitter.
<i>Orbitofrontal cortex</i>	Part of the frontal cortex nearest to the eyes, connected with limbic structures.
<i>Radiotracer</i>	Radioactive substance injected in small (trace) amounts for diagnostic purposes.

Serotonin

A neurotransmitter among others related to mood and anxiety.

Tomography

Three-dimensional reconstruction of brain maps from radiation given off by the brain (emission tomography) or from shadows of traversing rays (transmission scan).

Imaging Methods

Positron Emission Tomography

Positron emission tomography (PET) uses a scanner to detect the two gamma photons traveling in opposite directions that result from the annihilation of a single positron. The origin of these photons can, therefore, be localized on a straight line between the two detectors registering a coincident signal. Although the energy from positron emission is relatively high, the emitters have a short half-life (minutes), which keeps the administered dose of radiation low. However, a particle accelerator (cyclotron) and a radio chemist are required to generate the radio-emitting isotopes and to synthesize the required compounds *in situ*. Positron emitters in common use are ^{18}F -fluoro-deoxyglucose (FDG), which is taken up into neurons just like the energy provider glucose, but then is not further metabolized so that it reflects the regional pattern of brain activity. Cerebral blood flow markers, such as ^{15}O -labeled water, give an almost identical distribution of activity to FDG. ^{11}C and ^{18}F can be incorporated into many receptor ligands to provide radiolabels representing specific binding to these receptors. Examples are ^{11}C -raclopride, a dopamine $\text{D}_{2,3}$ receptor ligand, ^{11}C -methyl-spiperone, a $\text{D}_{2,3,4}$ ligand, and

Figure 1 Principles of localizing source of radiation in PET and SPECT (see text).

^{18}F -fluoro-dopa, a marker of dopamine synthesis. The spatial resolution of PET is in the region of 5 mm.

Single Photon Emission Computerized Tomography

Radioisotopes that emit photons in the gamma frequency range with a radioactive half-life in the range of hours can be employed as single photon emission computerized tomography (SPECT) ligands. In contrast to PET, in which theoretically all coincident signals are exploited to localize the source of the radiation, SPECT needs to restrict the field of view of the detectors with collimators in order to localize the origin of the signal (Figure 1). Collimators absorb much of the activity from the field of vision, so that SPECT is less sensitive than PET. Tracers used are $^{99\text{m}}\text{Tc}$ -labeled exametazime and bismuth and ^{123}I -labeled IMP for perfusion imaging and, e.g., ^{123}I -iomazenil for (benzodiazepine) receptor binding. Modern SPECT cameras have a resolution of 5–10 mm.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is based on manipulating the resonance frequencies of nuclei, such as ^1H protons or ^{31}P phosphorus, by systematically changing magnetic field strength across the imaging volume. As magnetic field strength is directly proportional to the magnetic resonance frequency of hydrogen nuclei in H_2O , their spatial position can be frequency encoded. The strength of signal in the frequency domain (k space) then corresponds to the proton density at a particular spatial coordinate. Apart from proton density, relaxation times such as T_1 and T_2^* are extracted from such frequency domain data and provide important information in illness and during the normal functioning of the brain. The resolution for MRI is in the 1–2 mm range.

Functional MRI

T_2^* changes, for example, occur when oxygenated hemoglobin loses its oxygen. In active brain regions, regional blood flow increases beyond the consumption of oxygen, so that a local excess of oxygen-saturated
